Abstract

Lignin, one of the most abundant natural polymer after cellulose has attracted great attention in academia as well as in industry for miscellaneous applications. Lignin also exhibits very high potential as a renewable sustainable resource for galaxy of high value biochemicals. Due to typical structure of lignin, it can be converted into different type of useful products. From lignocellulose biorefinery prospective point of view, it can be regarded as an economic bio product and can also be used as filler in several polymers to form blend or composites. Recently lignin based hydrogels have shown excellent performance for removal of various pollutants from

water. The adsorption properties of lignin based hydrogels can further be improved by using the combination of nanomaterials and lignin that results in promising hydrogel nanocomposites. In nature, most abundant structures are formed by the combination of lignin, cellulose and hemicelluloses. So, in this article, we have attempted to comprehensively review the research work carried out in the direction of usage of lignin based hydrogel for removal of toxic pollutants including metal ions and dyes.

Keywords: Lignin; structure; hydrogel; nanocomposite; water treatment; metal ions; dyes.

1. Introduction

Hydrogels belongs to a category of soft matter comprising of polymeric cross-linked three-dimensional structure [1,2]. The characteristics of hydrogels such as flexibility, elasticity and permeability are attributed to their high water absorption ability [3]. They shows both half liquid-like and half solid-like properties [4,5]. Three-dimensional structure of hydrogel is generally organized by (a) chemical cross linking and (b) physical cross linking [6,7]. Coordination bonds, electrostatic interaction, hydrogen bonding and hydrophobic interaction are responsible for the formation of physically cross-linked hydrogels. The aqueous solution of amphiphilic organic molecules [8] or inorganic nanoparticles [9] can produce hydrogel through supramolecular chemistry. Physically cross-linked hydrogels have sol–gel phase transition [10] on exposure to external stimuli [11,12]. On the other hand, change in external conditions such as pH [13], electric field [14], temperature [15,16] and ionic strength [5] leads to the volume phase

transitions [17] in chemically cross linked hydrogels. These hydrogels exhibit permanent three dimensional networks. Because of these features, hydrogels have potential use in various applications such as superabsorbent, bio actuators, microfluidic devices, packaging materials catalyst supports and biomedical materials [18–26]. Super absorbent characteristics of hydrogels are attributed to their ability to absorb huge quantity of water, about 10-20 times as compared to their original molecular weight, after absorbing water hydrogel achieves a swollen state [27,28]. On the other hand, Xerogels (an important class of gels) may be defined as hydrogels without water, dried hydrogels, water is removed from hydrogels network. While, aerogels exhibit the removal of water molecules from hydrogels network with no deformation of structure [29]. The diffusion process of hydrogel depends on their structure and the thermodynamic behavior of components used in the formation of hydrogel network [7]. The swelling capability of a hydrogel is linked to the porosity of network and porosity generally depends on (a) crosslinking density and (b) attraction between hydrogel and aqueous solution. The porosity of structure also permits the adsorption of pollutants from wastewater or water [30,31]. Water exists in different forms in the network of hydrogel. The presence of water in hydrogel can be divided into four types [32] as: (a) free water present in outer part that can be removed easily or easily extractable bulk water of hydrogel structure, (b) physically entrapped water, exist in interstices of network named interstitial water, (c) chemically attached bound water through functional groups and linked directly to network, it cannot be removed under normal conditions from hydrogel network, (d) semi bound water, neither free nor bound water, but exist in between these two type of water. DSC thermogram can be used to identify and characterize the water present in hydrogel [33]. The development of network of hydrogel depends on the kind and quantity of cross linker used in the formation of hydrogel. Different types of cross linkers are required for different

applications [32]. Cross-linkers can be classified as (a) physical and (b) chemical cross-linkers. Physical cross linking includes hydrogen bonding, freeze thawing, thermo gelation and charge interactions [34–39]. Chemical cross linking in hydrogels may be due to the radical polymerization, high energy irradiation, enzymes and reaction of functional groups [40–44]. Insolubility of hydrogels is because of the presence of chemical and physical cross links. At equilibrium swelling state, dispersion and cohesive forces of hydrogel becomes equal [32,45]. Dipole–dipole, electrostatic and hydrophobic forces can contribute to cohesive forces, covalent bond is usually responsible for cohesive forces. Biopolymers based materials such as hydrogels and fibres are lighted topic and represent the most promising biorenewable materials for various applications [46–49]. Tunable and degradation characteristics are advantages of biopolymer based hydrogels. The use of lignin for different applications has been reported earlier and well-reviewed due to the inherent advantages of lignin [48] [50] [51–56]. So, in this article, we will primarily focus on the recent progress carried out in lignin based hydrogel material for water treatment.

2. Lignin Structure

In 1838, the structure of wood was first elucidated by Anselme Payen, French scientist [57]. He obtained a material by reacting wood with nitric acid which looks like thread called cellulose. There was substance enriched of carbon even after the extraction of cellulose. Anselme Payen used the better extraction process and successfully obtained a new encrusting substance named lignin [56]. It was found in 1890 that lignin did not belong to polysaccharides and cellulose and lignin were differing by methoxy groups [56]. Lignocellulosic biomass has attracted great attention because of its accessibility and lack of contest with supply of feed[58] [59] [60] [61]

[62,63]. Lignocellulosic biomass made up of three components [64]: (a) cellulose, (b) hemicellulose and (c) lignin (**Figure 1**) [65] [66] [67] [68]. Study regarding lignin is still going on because of its specific characteristics.

Lignin is found in plant and most of the plant biomass can consist of 30% of lignin [69]. In earth, after cellulose, lignin is most abundant aromatic natural complex polymer [52] [70] [71]. Strength, integrity and inflexibility [72] of plant cell are provided by binding of lignin with cellulose and hemicelluloses [73] [74] [75] as shown in **Figure 2 (a)**. Several pre-treatment processes are used for the extraction of lignin from different lignocellulosic resources. Most of the currently used pre-treatment processes have been found to generate toxic compounds and inhibitors during the lignin processing (**Figure 2b**)

Amorphous lignin polymer has significant use in fluid flow, pathogen resistance and response to stress [76]. Such lignin-polysaccharides network helps in bio refining by cell walls. Monolignols-p-coumaryl, sinapyl and coniferyl alcohols [77,78] are the three phenylpropanoid from which lignin is derived giving p-hydroxyphenyl (H), syringyl (S) and guaicyl (G) units respectively. Generally, the linkages β -O-4', β -5', α -O-4', 4-O-5', β - β ' exist in between the subunits, β -1' and 5-5' linkages also exist but in small amount. 0-5/95-100/0, 0-8/25-50/46-75 and 5-33/33-80/20-54 are the H/G/S ratio in softwood, hardwood and grasses respectively [79]. The structure of lignin can be best depicted by common empirical chemical formula. The common empirical chemical formula is based on C₉ formula which represent the nine carbon atom molar ratio with respect to other elements, formula shows common repeating unit which are formed by monolignols. C₉H_{7.92}O_{2.40}(OCH₃)_{0.92} and C₉H_{7.49}O_{2.53}(OCH₃)_{1.39} [80] are the C₉ formula of softwood and hardwood lignin respectively. The difference between softwood and hardwood is due to their different monolignols ratio.

Freudenberg [81] (1965), Adler [82] (1977), Brunow et al. [83] (1998) and Gellerstedt [84] (2007) respectively developed structure for spruce (softwood) lignin and beech (hardwood) lignin structure was produced by Nimz [85] (1974). According to Adler [82] and Gellerstedt [84], models for structure of lignin can be represented in different ways. The structure of type 1 and type 2 lignin existing in plant was given by Gellerstedt et al. [84,86]. The weight/weight percentage (w/w %) of spruce lignin is 48 in type 1 whereas it is 40 in type 2 [84,86]. Glucomannan-lignin-xylan (w/w = 9:9:1) and xylan-lignin-glucomannan (w/w = 2:3:1) are the complexes contained type 1 lignin and type 2 lignin respectively. Type 1 lignin is attached directly to cellulose strands via hydrogen bridges. The repeating units of type 1 lignin are connected by the distinct linkages. Type 2 lignin is situated across the cellulose fibrils enclosed in type 1 lignin. Generally, ether bond linkage i.e. β -O-4' exist in between the repeating units for both softwood and hardwood lignin. About 50% and 60% [53,87] of β -O-4' ether bonds can be found in softwood and hardwood lignin respectively.

3. Lignin Hydrogels for Water Purification

Lignin based hydrogels have been reported to be used in water treatment for removing different pollutant [88–102] from water or wastewater (**Table 1**). Recently, Li et al. synthesized highly porous lignosulfonate based graphene hydrogel through hydrothermal method for lead ion (Pb^{2+}) [88] adsorption from water. A very high adsorption capacity i.e. 1210 mg g^{-1} was reported for removal of Pb^{2+} . The dispersion of lignosulfonate/graphene oxide aqueous solution comprising 1 mg mL^{-1} graphene oxide and 0.050 mg mL^{-1} lignosulfonate before and after the treatment by hydrothermal is demonstrated in **Figure 3a**.

The developed lignosulfonate based graphene hydrogel having mass 5.4 ± 0.2 mg with 98.6% water was thin and intense sufficient to tolerate about 100 g weight by three hydrogels. (**Figure 3b and c**). On application of tension, some deformations were detected which were disappeared shortly. Highly porous three dimensional structure of lignosulfonate based graphene hydrogel was confirmed by SEM images as represented in **Figure 3d-f**. The variable pore sizes (nanometers to micrometers) of this hydrogel were observed. High specific surface area of $459.3 \text{ m}^2 \text{ g}^{-1}$ was provided by the micro and mesoporosity while macroporosity insured approachability to such surface. Three dimensional porous structures were developed by hydrophilic aerated groups and pi-pi interaction between the sheets of grapheme (**Figure 3**).

Dual role i.e. dispersant and functional agents were played by the lignosulfonate in the formation of hydrogel. Hydrothermal process for the synthesis of this hydrogel occurred through the aggregation of graphene oxide sheets due to pi-pi interactions whereas lignosulfonate did not undergo any change in its structure on hydrothermal treatment. The homogeneous dispersion was given by negatively charged lignosulfonate to graphene oxide sheets via electrostatic repulsion. The interaction between lignosulfonate and reduced graphene oxide sheets was explained by noncovalent interactions such as pi-pi conjugation and hydrogen bonding as shown in **Figure 4**.

Importantly, lignosulfonate based graphene hydrogel was fabricated in a column-packed device (**Figure 5a**) for the fast Pb^{2+} removal from aqueous solution with excellent adsorption capacity i.e. 308 mg g^{-1} in 40 min, which was 1210 mg g^{-1} in 240 min for conventional shaking adsorption method. The column-packed adsorption gave effective way to use the interior pores of lignosulfonate based graphene hydrogel for the adsorption of Pb^{2+} ions. Adsorption experiments were performed for Pb^{2+} ions by using batch method with 40 ml Pb^{2+} aqueous solution, 400 mg mL^{-1} of Pb^{2+} initial concentration. The graph between adsorption capacities and contact times are

given in **Figure 5b**. Moreover, this hydrogel showed excellent reusable and regeneration study after many adsorption–desorption (**Figure 5c**). The 90% and 82% adsorption capacities were preserved after five and ten cycles respectively.

In another work, adsorption capacity of 235 mg g^{-1} was reported for adsorption of Pb^{2+} by using lignin grafted polyacrylic hydrogel [89]. Closed honeycomb cell morphology was obtained for polyacrylic, while porous and rough surface with enhanced surface was observed by grafting of polyacrylic acid onto lignin. The mechanism of Pb^{2+} adsorption was explained on the basis of ion exchange or electrostatic attraction [89].

Yin et al. synthesized cellulose-lignin composite hydrogel using ultrasonic irradiation for the removal of Pb^{2+} from water [90]. The optimum adsorption capacity of 786.16 mg g^{-1} was reported in this hydrogel for Pb^{2+} adsorption. Kwak et al used silk sericin and lignin blend as adsorbent from agricultural by-products for the effective removal of hexavalent chromium (Cr^{6+}) with adsorption capacity 139.86 mg g^{-1} [91]. Dax et al. developed hemicelluloses based hydrogels for the application of removal of pollutants such as arsenic and chromium ions from aqueous solution [92]. Two molar mass molar of 7.1 and 28 kDa of O-acetyl galactoglucomannan macromonomers (GGM) with methacrylate groups (MA) were applied as crosslinker in the formation of hydrogels utilizing monomer of [2-(methacryloyloxy)ethyl]trimethylammonium chloride. The reaction occurred between O-acetyl galactoglucomannan and glycidyl methacrylate to form O-acetyl galactoglucomannan macromonomers through transesterification. Hydrogels with different GGM were represented as GGM5-MA ($M_n = 4.7 \text{ kDa}$) and GGM22-MA ($M_n = 21.5 \text{ kDa}$). It was found that swelling capacity for GGM5-MA was 3.7 times higher as comparison to GGM22-MA. The swelling capacity was visualized in simple way by showing one radical and one polymer chain arising in

the reaction system (**Figure 6**). Polymer chain was attached to one GGM-MA (**Figure 6, (1)**), growth began and attached to second GGM-MA. Then, third GGM-MA chain came in contact with active polymer chain (**Figure 6, (2)**). The flexibility of three chains was still maintained for both hydrogels (GGM5-MA and GGM22-MA). The difference in swelling potential was observed when three GGM-MA chains were merged (**Figure 6, (3)**). The swelling capacity of hydrogel was decreased at this stage and it was difficult for chains to depart. The swelling ability was reduced due to the formation of strong crosslinked network in hydrogel utilizing GGM22-MA as crosslinker as highlighted in red (**Figure 6(4)**). Initially at time 0, brownish color was shown by dried synthetic polymer, which was changed to transparent after swelling in 22 h. **Figure 7** shows the SEM images of freeze dried GGM based hydrogel at three magnifications. The unevenly distributed particles having smooth surface was seen at low magnification (**Figure 7a**). The porous surface was observed after drying process (**Figure 7b**). At high magnification, extended surface of this hydrogel was found (**Figure 7c**). The potential of the newly synthesized hydrogels was investigated for wastewater treatment by carrying out different sorption experiments at pH 9. **Figure 8** demonstrates the sorption (S) of the developed hydrogels as a function of the swelling rate (Q). It was concluded from this study that the hydrogels in general exhibited the good sorption capacities for both arsenates/ chromates as the capacities were found more at higher swelling rate.

A lignin hydrogel based on bentonite/sodium lignosulfonate/acrylamide/maleic anhydride (BLPAMA) was prepared for the adsorption of lead ions (Pb^{2+}) and exhibited high adsorption capacity of 322.70 mg g^{-1} [93]. In this work, the behavior of the synthesized hydrogels was studied as a function of different reaction parameters such as initial pH, contact time, adsorbent dosage, temperature, concentration of Pb^{2+} , and additive electrolyte. **Figure 9** shows the

mechanism for the synthesis of BLPAMA hydrogel. Different characterization techniques such as FTIR, TGA, XPS and SEM were used for detailed elucidation of the BLPAMA hydrogel adsorption mechanisms on a micro level. **Figure 10** shows the comparative surface morphologies of both the BLPAMA and Pb^{2+} loaded hydrogel (BLPAMA) and significant changes were observed for both the hydrogels confirming the successful adsorption of metal ions. These results were further supported by the XPS spectra and were also in agreement with the experimental results of the effect of initial pH/ the ionic strength (**Figure 11**). The mechanism of adsorption of lead ions onto this hydrogel was explained primarily by ion exchange and chelation. In another study, the effect of lignin on the adsorption capacity of starch/acryl amide-based hydrogels for the adsorption of Cu^{2+} and Ni^{2+} was investigated [94]. In this work interpenetrating polymer network (IPN) were created for the adsorption of metal ions. Scanning electron microscopy (SEM) and infrared spectroscopy was employed to investigate the morphology and functional groups incorporated onto the surface. Fick's law was further used to study the behavior of hydrogels in water. All the IPN based hydrogels were found to show Fickian water transport mechanism and were proposed to have a high potential to develop metal ion-collector membranes [94]. Grafting of acrylic acid monomer on lignosulfonate backbone was carried out using N,N' -methylene-bis-acrylamide and laccase/t-BHP(tert-butyl hydroperoxide) as cross linker and initiator respectively [95]. **Figure 12** shows the proposed schematic for synthesis of LS-g-AA hydrogels. The successful grafting of the monomer was confirmed using FTIR (**Figure 13**).

Lignosulfonate-g-acrylic acid showed high methylene blue dye adsorption capacity of 2013 $mg\ g^{-1}$. The effect of pH, time and methylene blue dye concentration on adsorption capacity was studied. Excellent reusability was shown by lignosulfonate grafted acrylic acid hydrogel with

adsorption capacity 1757 and 1681 mg g⁻¹ for 3 and 4 cycle respectively. The photograph of lignosulfonate grafted acrylic acid hydrogel is shown in **Figure 14**. Transparency of lignosulfonate grafted acrylic acid hydrogel was interrupted by the formation of bubbles, which were due to entraining air during stirring of reaction. Tang et al. have reported their studies on the preparation of lignin sulfonate-based mesoporous materials (LSMMs) for adsorbing malachite green from aqueous solution [96]. Copolymer adsorbent was synthesized by grafting of acrylic acid and acrylamide onto backbone of lignin sulfonate for the application of malachite green dye removal from water [96]. **Figure 15** shows the schematic of the structure unit of the LSMMs. Adsorption capacity, 150.376 mg g⁻¹ was reported for adsorption of malachite green (MG) dye. This synthesized material was mesoporous confirmed by using N₂ adsorption/desorption. The mesoporous structure was affirmed from capillary action at around $P/P_0 = 0.45-1.0$ and diameter of 3.8 nm. High BET surface area of 118 m² g⁻¹ for lignin sulfonate-g-poly (acrylic acid-r-acrylamide) was mentioned. The adsorption of the malachite green (MG) dye was confirmed through FTIR (**Figure 16**) and SEM. The structure of lignin sulfonate-g-poly (acrylic acid-r-acrylamide) (**Figure 17b**) was rough and porous in comparison to lignin sulfonate (**Figure 17a**). Hence adsorption efficiency was improved with the presence of pores in lignin sulfonate-g-poly (acrylic acid-r-acrylamide). The hydrogel of acylated hemicelluloses, acrylic acid and sodium lignosulfonate was prepared by using initiator ammonium persulfate and N,N,N',N'-tetramethylethane-1,2-diamine with high adsorption capacity of for 2691 mg g⁻¹ methylene blue dye [97]. The effect of sodium lignosulfonate on the morphology of prepared hydrogel was studied in detail. The honeycomb-like morphology was observed for all samples. The pore size of hydrogel was not affected by the sodium lignosulfonate concentration. In this work, sodium lignosulfonate dosage was found to exhibit a

strong influence on the swelling ratio as well as the adsorption capacity. The adsorption kinetics was fitted with pseudo-second-order kinetics and isotherm well fitted by Langmuir isotherm. Even after the further cycle, the hydrogel was found to exhibit an approximately 80% adsorption efficiency and was proposed to be a promising material for dye wastewater treatment [97]. Luo et al. have also developed hydrogel of kraft lignin-*N*-isopropyl acrylamide and applied for the removal of methylene blue dye from aqueous solution [98]. Gassara et al. have also reported their studies on the usage of manganese peroxidase, lignin peroxidase and laccase with polyacrylamide hydrogel and pectin for the degradation of bisphenol A [99]. Bisphenol A degradation was low by using free enzyme while it was high with encapsulated enzymes on hydrogel. **Figure 18** shows the possible pathways of degradation of bisphenol A. The enzyme activity was found to be increased in the presence of pectin.

4. Conclusion & Future Trends

The number of published articles is increasing [53] continuously on synthesis and characterization of lignin based materials for different types of applications as indicated in **Figure 19**. The published articles are more on biopolymers such as starch and cellulose in comparison to lignin. This is due to the following reasons: (a) biopolymers such as cellulose and starch can be applied in diverse applications and (b) still there are several issues related to lignin valorization such as complexity, economical and technical aspects. Technologies for the production of lignin can be improved in order to increase the further interest in lignin based materials.

Nanomaterials have been utilized for various applications [103–105]. The mechanical strength as well as adsorption efficiency of lignin hydrogels can be improved by incorporating

nanomaterials into their matrix [25,30,31,106–110]. To the best of our knowledge, up to date there is only one article on lignin based hydrogel using graphene oxide [88] as already discussed in this review. Hence different nanomaterials such as silicate nanoparticles, metal oxide nanoparticles, nanocellulose, graphene, carbon nanotubes and graphene oxide can be used with lignin hydrogels to develop new materials for the removal of various pollutants from water or wastewater [110-115].

Table 1. Various lignin based materials utilized for water treatment.

Lignin Based Material	Pollutant	Reference
Lignosulfonate based graphene hydrogel	Pb ²⁺	[88]
Lignin grafted polyacrylic hydrogel	Pb ²⁺	[89]
cellulose-lignin composite hydrogel	Pb ²⁺	[90]
Silk sericin and lignin blend adsorbent	Cr ⁶⁺	[91]
Hemicelluloses based hydrogels	As ⁵⁺ and Cr ⁶⁺	[92]
Bentonite/sodium lignosulfonate/acrylamide/maleic anhydride hydrogel	Pb ²⁺	[93]
Lignin/peat/starch/acryl amide-based hydrogel	Cu ²⁺ and Ni ²⁺	[94]
Lignosulfonate-g-acrylic acid hydrogel	Methylene blue	[95]
Lignin sulfonate-g-poly (acrylic acid-r-acrylamide) copolymer adsorbent	Malachite green	[96]
Acylated hemicelluloses/acrylic acid/sodium lignosulfonate	Methylene blue	[97]

hydrogel		
Kraft lignin- <i>N</i> -isopropyl acrylamide hydrogel	Methylene blue	[98]
Manganese peroxidase/lignin peroxidase/laccase/polyacrylamide/ pectin hydrogel	Bisphenol A	[99]
