Abstract:

Highly conductive titanium nitride (TiN) has a strong anchoring ability for lithium polysulfides (LiPSs). However, the complexity and high cost of fabrication limit their practical applications. Herein, a typical structure of hollow carbon nanospheres@TiN nanoparticles (HCNs@TiN) was designed and successfully synthesized via a microwave reduction method with the advantages of economy and efficiency. With unique structural and outstanding functional behavior, HCN@TiN-S hybrid electrodes display not only a high initial discharge capacity of 1097.8 mA h g⁻¹ at 0.1C, but also excellent rate performance and cycling stability. After 200 cycles, a reversible capacity of 812.6 mAh g⁻¹ is still retained, corresponding to the low decay rate of 0.13% per cycle of the initial capacity, which are much better than those of contrast HCNs-S electrodes.

1. Introduction

To meet the growing demands for advanced energy storage system, Li-S batteries are considered as one of the most promising candidates for the next generation large-scale energy storage devices due to the extraordinary theoretical specific capacity and energy density of sulfur (1675 mAh g⁻¹ and 2600 Wh kg⁻¹ or 2800 Wh L⁻¹) [1]. However, the low electron conductivity of sulfur ($\sim 10^{-30}$ S cm⁻¹) and the dissolution of lithium polysulfides in organic electrolytes are two key obstacles, which hinder Li-S batteries commercialization process [2].

To counter these problems, an effective method is to combine sulfur nanoparticles with other conductive matrix materials [3]. Over the past few years, carbonaceous materials, such as carbon spheres [4-6], carbon nanotubes [7], porous carbon fibers [8], carbon nanoribbons [9] and graphene [10], have been widely introduced in Li-S batteries as sulfur host materials because of their intrinsic high conductivity, high porosity, high surface area, diversity in nanostructures and easy availability [11]. Among them, hollow carbon nanospheres are considered as very promising matrix materials due to their fully enclosed structure and large inner cavity [12-15]. It basically solves the problem of electrical insulation and the large volumetric expansion of sulfur. However, these nonpolar carbon based nanocomposites can only provide a weak physical adsorption to the LiPS. Once the polar polysulfides are dissolved in the organic electrolyte, the reutilization of sulfur becomes very difficult, which makes the sulfur/carbon composite cathodes still generally suffer from low cycle stability.

Except for encapsulating sulfur within the pores of carbon materials, the strong chemical interaction effect between LiPSs and the matrix has attracted more attention

and interest from the researcher. Some of materials such as conductive polymers [16], metallic oxide [17-19], sulfides [20, 21] and hydroxides [22] have been combined with carbon materials as the sulfur host because of their strong chemical affinity with LiPSs. However, most of the above chemical adsorbents are semiconducting or even electronic insulating, which seriously impedes electron transportation within the cathode. Therefore, there will be an important value in introducing highly conductive polar materials into the sulfur electrode to alleviate the above issues.

Recently, early-transition-metal carbides or nitrides having high conductivity, a polar surface, electrocatalytic activity and low cost have been demonstrated as good electrode additives for improving the cycling stability of Li-S batteries [23,24]. Yu and co-workers presented a strategy that is decorating metal carbide nanoparticles (W_2C , Mo_2C and TiC) as active sites on CNFs as the electrodes [25]. Electrochemical tests demonstrate that carbide nanoparticles could improve both the cycling stability and rate capability of Li-S batteries *via* the dual effect of providing adsorption and catalytic ability. In addition, transition metal nitrides have no less performance than carbides. In 2016, a mesoporous TiN as sulfur host for Li-S batteries was first reported by Goodenough and co-workers [26]. This porous TiN could confine and encapsulate LiPSs by both chemical interactions and physical adsorption. Furthermore, TiN has high electrical conductivity and excellent chemical stability. All these properties make the hybrid TiN -S an excellent cathode. Most recently, the reaction mechanism of polysulfide catalyzed by TiN has been investigated in detail by Ding et al [27]. The density functional theory (DFT) calculations revealed that the long-chain Li_2S_8 tend to break down into two shorter chain segments due to the strong interaction of TiN . These efforts mentioned above indicated that TiN can be applied as ideal cathode material of Li-S batteries.

However, synthesis method of TiN usually involved a thermal reaction via ammoniation at prolonged high-temperature [26-31]. This process has some shortcomings, such as high time and energy consumption, environmentally unfriendly reactants and high-cost, and thus, is not a practical method for fabricating engineering materials in the bulk form. Besides, out of consideration for the overall energy density of the electrode, it is inappropriate to overuse the TiN as the host material for sulfur due to its relative high density.

Taking the above discussion into consideration, in this study, we use a one-step route to fabricate poly(aniline-co-pyrrole)(PACP) copolymer hollow nanospheres by the polymerization of pyrrole and aniline in Triton X-100 solution. And an effective sol-gel and microwave reduction method was designed and used to obtain a typical structure of hollow carbon nanospheres@TiN nanoparticles (HCNs@TiN) as the host materials for Li-S batteries. Particularly, PACP@TiO₂ can be transformed into the HCNs@TiN composite completely at 1200 °C for only 10 min by microwave heating reduction under a N₂ atmosphere. This method not only reduces the reaction temperature significantly through microwave heating but also can simplify the operation process effectively.

The host material made of HCNs@TiN exhibits several advantages as follows: first, the large inner cavity structure of hollow carbon nanospheres not only allows a high loading of sulfur but also effectively buffer the large volume change of sulfur during the procedure of lithiation and delithiation process. Second, the outer carbon shell can provide an effective conductive network to improve the electronic conductivity of sulfur cathodes and serves as a physical barrier to restrain the dissolution of polysulfides. Third, the well-distributed TiN particles coated on HCNs can act as an anchor to confine the shuttling effect of LiPSs via strong chemical interactions. As a consequence of these

favorable effects, the developed HCN@TiN-S composite with 62.86 wt% sulfur content delivers a high initial discharge specific capacity of 1097.8 mAh g⁻¹ at 0.1C with coulombic efficiency (≈98%), and retains a discharge capacity of 812 mAh g⁻¹ after 200 cycles, which are much better than those of the contrast HCNs-S electrodes.

2. Experimental Section

2.1. Preparation of PACP hollow nanospheres

The PACP hollow spheres were prepared by an oxidative polymerized method reported in previous works [31-33]. In particular, the polymerization was carried out in a thermal incubator at 0 °C. Initially, 0.9 g Triton X-100 and 900 ml deionized water were added to a beaker covered with polyethylene film and stirred 20 minutes. Then, 4.35 mL pyrrole and 5.7 mL aniline were added to the mixed solution. After 10 minutes, 120 mL of aqueous solution containing 27.45 g of ammonium persulphate as an initiator was added forming a homogeneous solution. After the reaction lasted for 12 h, the resulting precipitate was vacuum filtered, washed with deionized water several times and dried at 80 °C for 6 h. Finally, the sample was collected for further processing.

2.2. Synthesis of PACP @ TiO₂

TiO₂ layer was coated on PACP copolymer hollow nanospheres via a sol-gel method. Typically, 0.5 g of PACP was dispersed in a serum bottle with 150 mL of ethanol solution through sonication. After stirring for 30 min, 360 μL of tetrabutyl titanate (TBOT) in ethanol (the total solution volume is 50 mL) was added drop by drop under vigorous stirring and sealed immediately. After 1h, twisting the lid off, making the mixed solution in full contact with the air, the hydrolysis reaction was carried out at room temperature for 12 h under magnetic stirring. Finally, the PACP@TiO₂ hollow nanospheres could be obtained by vacuum filtration, washing with deionized water three

times and drying at 80 °C for 12 h.

2.3. Synthesis of HCNs @ TiN by microwave

At first, 0.5g PACP@TiO₂ was placed within a graphite crucible and inserted into a silicon carbide (SiC) tube which has a critical auxiliary heating effect. Then, the SiC tube was wrapped with asbestos and placed in a microwave furnace. The furnace was heated to 1200 °C at a very high rate of heating (generally within 5 min) under a N₂ atmosphere with a gas pressure of 20 kPa. Then the target temperature was maintained for 20 minutes and then furnace cooling. For comparison, the control group HCNs was prepared by direct carbonization of PACP under the same heating condition.

2.4 Characterization

Scanning electron microscopy (SEM) was carried out on a field emission SU-70 microscope. TEM images were obtained by a JEOL JEM2010 electron microscope. Wide-angle X-ray diffraction (XRD) patterns were acquired with a Bruker D8 Advance diffractometer using monochromated Cu-K radiation (40 kV, 200 mA). Data was collected from $2\theta = 20^\circ$ to 80° in a step of 0.02 with a scanning rate of 0.2° s^{-1} . Thermogravimetric (TG) analysis was performed on TGA-Q50 thermal gravimetric analyzer in a N₂ atmosphere at heating rate $10^\circ \text{ C min}^{-1}$. Raman spectra were collected using a Renishaw inia Raman Microscope with an excitation laser wavelength of $\lambda = 514.5 \text{ nm}$. The N₂ adsorption/desorption isotherms were measured using an ASAP 2020 (Micromeritics Co.) at 77 K. The surface area was calculated according to the Brunauer-Emmett-Teller (BET) model based on adsorption data in the partial pressure (P/Po) range of 0.10-0.20. The total pore volumes and pore-size distributions were estimated from the amount of nitrogen adsorbed at P/Po=0.99. The pore size distribution was calculated by the original density functional theory (DFT). X-ray photoelectron spectroscopy (XPS) was conducted on a Microlab 350 spectrometer employing a

monochromatic Mg-K α X-ray source.

2.5 cell fabrication and electrochemical performance test

For the electrochemical measurement of these composites, the HCNs@TiN and HCNs were admixed with acetylene black and LA133 binder in a weight ratio of 80:15:5 to form a homogeneous slurry and then the slurry was blade cast onto aluminum foils and dried at 60 °C for 12 h under vacuum and then cut into discs with a typical diameter of 16 mm. The mass loading of sulfur in these working electrodes were approximately 1 mg cm⁻². The 2016 coin cells assembly was conducted in an Ar-filled glove box (O₂ and H₂O level < 0.1 ppm). The separator was Celgard2400 (America) micro-porous polypropylene membrane and Li metal was used as the counter electrodes. The electrolyte was composed of 1 M bis(trifluoromethane) sulphonamide lithium salt and 0.1 M LiNO₃ in a mixture of 1,3-dioxolane and 1,2- dimethoxyethane (1:1 by volume). Galvanostatic discharge-charge tests were conducted on a Land automatic batteries tester (Land CT2001A, Wuhan, China) with voltage window of 1.8-3.0 V versus Li⁺/Li. The current density was based on the weight of sulfur (1 C = 1670 mA g⁻¹). Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) was performed on an electrochemistry workstation (CHI660D).

3. Results and discussion

Fig.1 outlines the procedure for the preparation of HCNs@TiN. Initially, the PACP hollow nanospheres were synthesized through a one-step route by the polymerization of pyrrole and aniline in Triton X-100 solution. As shown in the SEM images in Fig. 2a, the PACP nanospheres with uniform size and smooth surface are obtained. The TEM image (Fig. 2b) of PACP shows hollow nanospheres with an average inner diameter of 60 nm and an average outer diameter of 120 nm. Fig. 2c exhibits that PACP is amorphous structure and no lattice fringe of graphite has been observed.

Fig.1 A schematic illustration of the procedure for the preparation of HCNs@TiN-S.

After that, selecting tetrabutyl titanate as a titanium source, a thin uniform layer of amorphous TiO₂ was coated on the surface of PACP hollow nanospheres via a sol-gel reaction. Then the obtained PACP@TiO₂ composite was quickly heated to the 1200 °C and treated for 10 min through microwave heating reduction under a N₂ atmosphere, and HCN@TiN particles were obtained. Fig. 2(d and e) show that HCNs@TiN retained a perfect nanospherical morphology but presented a smaller average inner diameter of about 50 nm and an average outer diameter of about 100 nm. It indicated that a large number of oxygen-containing functional groups of PACP are lost in the process of microwave reduction. In contrast to the smooth surface of PACP, many nanoparticles which had a size distribution of 10-50 nm were homogeneously decorated on the surface of the hollow carbon sphere. The control group HCNs had a smooth surface and presented an average inner diameter of about 50 nm and an average outer diameter of about 96 nm, as shown in Fig. S1. HRTEM images obtained from three regions (I, II, III in fig. 2f) clearly show that some lattice fringes appear on the carbon matrix and

nanoparticles. The lattice fringe in region “I” was found to be ca. 0.335 nm, corresponding to the d_{002} spacing of graphite. Obviously, graphite crystallites was generally observed in the carbon spherical shell after microwave reduction (region I), which helps to enhance the electrical conductivity of carbon matrix. In addition, the lattice fringes in the region “II” and “III” were measured to be ca. 0.213 nm and 0.245 nm, corresponding to d_{200} and d_{111} spacing of TiN, respectively, which are good in agreement with the result by XRD (Fig. 4). Finally, HCNs@TiN-S composites were synthesized by a melt-diffusion method that encapsulates the sublimed sulfur into HCNs@TiN. The SEM images of HCNs-S and HCNs@TiN-S are shown in Fig.3. The corresponding elemental maps of HCNs@TiN-S indicate the homogeneous distribution of sulfur in this composite.

Fig.2 (a) SEM image and (b, c) TEM images of PACP; (d) SEM image and (e, f) TEM images of HCNs@TiN; (I–III) the corresponding HRTEM images marked with white rectangle in figure f.

The crystal structure of the samples was analyzed by X-ray diffraction (XRD). As

shown in Fig. 4, the HCNs samples exhibit two broad peaks that can be observed at 2θ values of around 25° and 43° with no detectable crystalline Bragg peaks, which is characteristic for amorphous structure. While five well-defined characteristic peaks at 36.5° , 42.4° , 61.5° , 73.7° and 77.6° for the (111), (200), (220), (311) and (222) planes corresponding to crystalline TiN (JCPDS no. 65-0414) were detected for the HCNs@TiN samples. The sharp bragg peaks indicate that the as-prepared TiN nanoparticles have good crystallinity. The peaks of elemental sulfur (JCPDS no. 74-1465) are visible in these two composites HCNs-S and HCNs@TiN-S. However, there is a peak at 20° for these tow samples, which match neither sulfur nor TiN. This peak may be ascribed to a different form of sulfur, namely rosickyit-type sulfur (JCPDS no. 13-0141), suggesting that S₈ is not the only form of sulfur present after sulfur infiltration by the melt-diffusion method [35].

The reaction involving transformation of TiO₂ into TiN nanoparticles could be described by the following equations:

Fig.4 XRD pattern of HCNs, HCNs@TiN, HCNs-S and HCNs@TiN-S. Green and red drop lines correspond to Sulfur (JCPDS no. 74-1465) and TiN (JCPDS no. 65-0414)

It is known that approximately 78% by volume of air is N_2 . Due to the low cost and high safety, we choose N_2 instead of NH_3 to provide a nitrogen source for the nitridation of TiO_2 . Since N_2 has a quite high chemical stability, it is very difficult to quickly obtain TiN below 1300 °C by conventional carbothermal reduction of TiO_2 under an N_2 atmosphere. In this work, however, only 10 min was taken to synthesize HCN@TiN particles with high purity at 1200 °C by the microwaves heating process. It is considered that the uniform and rapid inside out heating profile leads to a shortened reaction time. On the other hand, the accelerated diffusion between reactants by the non-thermal effects of microwaves has contributed to lower initial reaction temperature. Additionally, if the N_2 atmosphere is replaced by argon gas (Ar), the product of the reaction transforms into HCNs@TiC (Fig. S2). The results indicate that the N in the as-prepared TiN particles comes from N_2 rather than PACP itself.

By performing the thermogravimetric analysis (TGA) from room temperature to 450°C at a heating rate of 10°C min⁻¹ under a N_2 atmosphere (Fig. 4a). The sulfur contents in the HCNs-S and HCNs@TiN-S composite were determined to be 61.68% wt% and 62.86 wt%, respectively.

Fig.4 (a) TG curves of HCNs-S and HCNs@TiN-S composite; (b) Raman spectra of PACP, HCNs and HCNs@TiN.

Raman spectra are depicted in Fig. 5b. Four peaks around 153, 261, 412, 606 cm^{-1} correspond to the bending and stretching modes of TiN, which are consistent with the results in the previous report [36]. Moreover,, two characteristic peaks located at about 1350 and 1587 cm^{-1} were observed in the synthesized PACP, HCNs and HCNs@TiN, which respectively correspond to the D-band (disorder and defects) and G-band (graphitic) of carbon. The D-band usually corresponds to the vibrations of sp^3 hybridized carbon, while the G-band is related to vibrations of sp^2 -bonded ordered graphitic carbon atoms. The distant G bands existing in HCNs and HCNs@TiN indicate that these materials may have good electrical conductivity, which will be favorable for the fast transmission of electrons during the electrochemical reaction process [37]. The nitrogen (N_2) adsorption-desorption isotherms and pore size distribution profiles of PACP, HCNs and HCNs@TiN are shown in Fig. S3. The BET surface and total volume of PACP were calculated to be 39.4 $\text{m}^2 \text{g}^{-1}$ and 0.16 $\text{cm}^3 \text{g}^{-1}$, respectively, which increased to 54.9 $\text{m}^2 \text{g}^{-1}$ and 0.204 $\text{cm}^3 \text{g}^{-1}$ when transformed into HCNs@TiN (Table S1).

XPS measurements were carried out to confirm the surface compositions of HCNs@TiN. The survey spectra and high resolution Ti2p XPS spectra are shown in Fig.5 (a-b). After deconvolution of the Ti2p spectra, six peaks referring to three pairs of spin-orbit split doublets are detected from the HCNs@TiN, including Ti-N bond (Ti 2p_{3/2}, 455.6 eV; Ti 2p_{1/2}, 461.3 eV), Ti-O bond (Ti 2p_{3/2}, 458.5 eV; Ti 2p_{1/2}, 464.2 eV), Ti-N-O bond (Ti 2p_{3/2}, 456.9 eV; Ti 2p_{1/2}, 462.6 eV) [38, 39]. Based on these data, oxide/oxyntiride passivation layer was formed on the surface of TiN when the sample is exposed to ambient air. Previous research has shown that the hydrophilic Ti-O groups can provide a polar surface that would form strong chemical bonds with the polysulfde [40, 43, 39]. Moreover, the N 1s detailed spectrum of HCNs@TiN is shown in Fig.5 c,

presenting a broad peak can be split into two peaks at 397.0 and 397.4 eV associated with Ti-N and Ti-N-O bond, respectively, which is consistent with the Ti 2p spectrum [39]. Another small peak at higher binding energy can be ascribed to the chemisorbed nitrogen.

Fig.5 (a-c) The XPS spectra of HCNs@TiN, (a)XPS survey spectra of HCNs@TiN, (b) Ti2p XPS spectra of HCNs@TiN, (c) N1s XPS spectra of HCNs@TiN; (d) Digital picture of the Li₂S₆ static adsorption by HCNs and HCNs@TiN in DOL/DME (1:1, v/v) solution for 36h.

The surface interaction between HCNs@TiN and Li₂S_x was proved through visualized adsorption experiments. Typically, 20 mg HCNs and HCNs@TiN were added into a one sealed vial containing a 10 ml solution of Li₂S₆ (10 mmol) in 1,3-dioxolane (DOL) and 1,2-dimethoxyethane (DME), and the DOL/DEM is 1: 1 by volume. As shown in Fig. 6d, after standing for 36 h, the yellow Li₂S₆ solution containing HCNs@TiN becomes colourless, confirming that the HCN@TiN host can effectively trap the Li₂S_x during the charge/discharge process. However, comparing the solutions for the control groups, there is no colour change for the blank one, while for

the HCN sample, the color of the Li₂S₆ solution only changes from yellow to pale yellow. The experiment demonstrates that the polar TiN has a stronger adsorption ability for LiPSs than carbon materials.

To compare the electrochemical performance, HCNs@TiN-S and HCNs-S composites were respectively made as cathodes and Li metal as the anode in 2016 coin cells. Fig. 7a shows the corresponding profiles for the 1st, 2nd, and 3rd cycles in the voltage window of 1.8-3.0 V with a scan rate of 0.2 mVs⁻¹. During the cathodic scan in the CV profiles, two well-defined characteristic reduction peaks are located at 2.27 V and 2.03 V, which correspond to the transformation of the open ring of S₈ molecules to form long chain Li₂PSs (Li₂S_n, 4≤n<8), and then to the insoluble Li₂S_n (n=1 or 2), respectively. In reverse anodic scan process, two oxidization peaks at 2.34V and 2.39V were related to reversible conversion of solid Li₂S or Li₂S₂ firstly oxidized to short-chain Li₂S_n (n=3 or 4), and then further oxidized to long chain Li₂S₈ or cyclo-S₈. After one cycle, the CV peak positions of the second and third cycles almost overlapped, implying the outstanding electrochemical reversibility of HCNs@TiN-S.

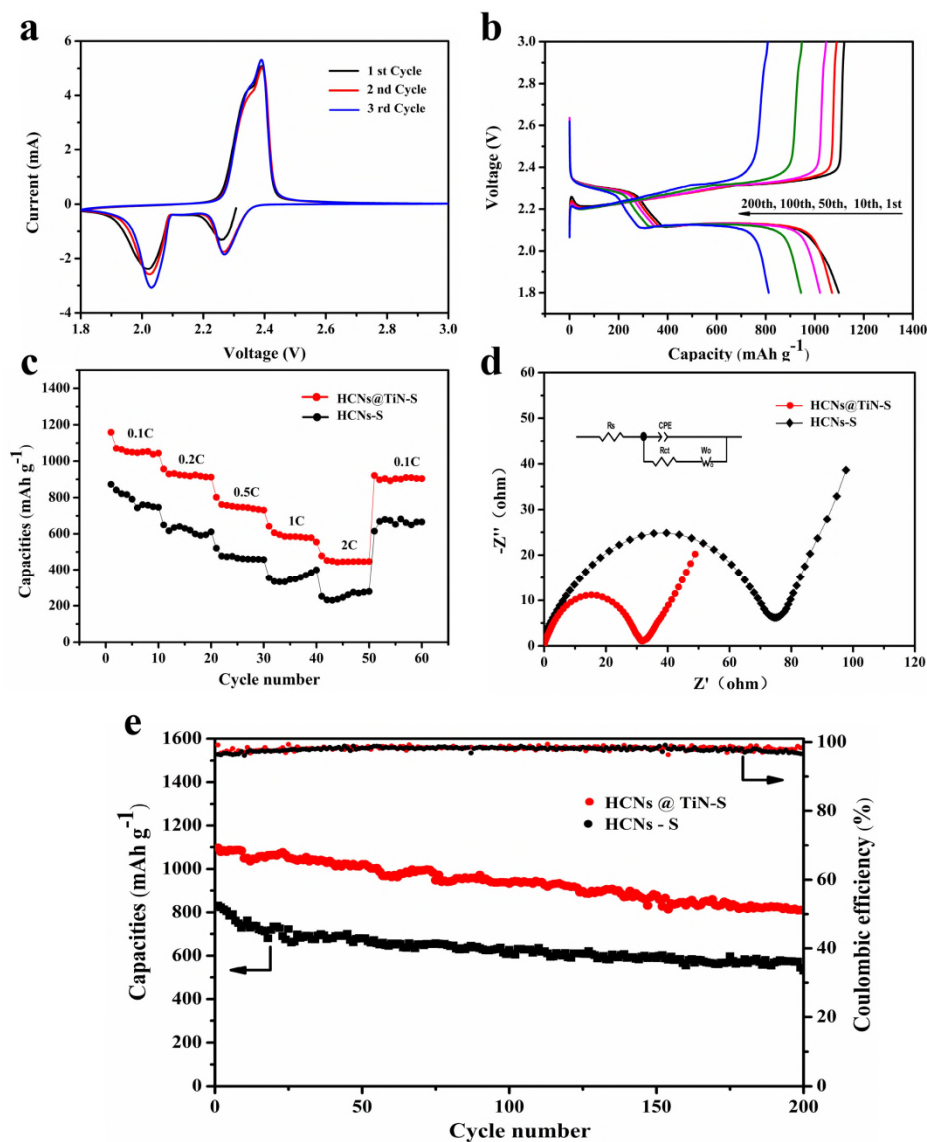

Fig.6 (a) Typical CV profiles and (b) charge-discharge profiles of HCNs@TiN-S cathode over different cycles at a current rate of 0.1C; (c) rate capacity of HCNs-S and HCNs@TiN-S, (d) EIS spectra before cycling and (e) cycling performance of HCNs-S and HCNs@TiN-S cathode at 0.1C.

Fig. 7b shows the galvanostatic charge/discharge profiles of the HCNs@TiN-S composite electrode over different cycles at a rate of 0.1C. The profiles show two discharge plateaus at around 2.3 and 2.1 V, representing the different stages of the redox reactions of sulfur. These results are basically in accordance with the CV results discussed above.

The rate capacities of the two composite electrodes were evaluated at different

discharge rates from 0.1 to 2C, as shown in Fig. 7c. It can be seen that the HCNs@TiN-S cathode shows much better rate capacity than that of the HCNs-S cathode. The average discharge capacity of HCNs@TiN-S at 0.1, 0.2, 0.5, 1 and 2 C are 1062, 925, 752, 589 and 450 mAh g⁻¹, respectively. Then, when the current rate switches back to 0.1C, the specific capacity can be largely recovered to 921 mAh g⁻¹ after 50 cycles. In contrast, the HCNs-S electrode exhibits obviously lower discharge capacities, the specific capacity at 0.1C, 0.2C, 0.5C, 1C, 2C rates are 790, 619, 471, 355 and 255 mAh g⁻¹, respectively.

To further understand the different kinetics of the HCNs@TiN-S and HCNs-S cathode during the electrochemical reaction, EIS data of both electrodes are collected before cycling in a frequency range of 10 mHz to 100 KHz. As shown in Fig. 6d, it can be observed that both composite electrodes are composed of a semicircle in the high frequency region representing the charge transfer process, and a sloped line in the low frequency region corresponding to a semi-infinite Warburg diffusion process, which is related to the ion diffusion in the electrode. The charge transfer resistance (*R_{ct}*) of the HCNs@TiN-S (17.92 Ω) is lower than that of HCNs-S (77.03Ω). Because of both cathodes containing approximately the same content of sulfur, the different charge transfer resistance could be attributed to the well-distributed coating TiN particles on HCNs, which shows better ability to facilitate the charge transfer for surface reaction than the single carbon materials.

The long-term cycling performance of the HCNs@TiN-S and HCNs-S cathode materials was measured at a rate of 0.1C. As shown in Fig. 7e, the HCNs-S electrode suffers from a sever capacity fade with a low capacity of 529.9 mAh g⁻¹ after 200 cycles, showing a high decay rate of 0.18% and a low capacity retention of 63.7% of the original capacity (831.3 mAh g⁻¹). In contrast, the original specific discharge capacity

of the HCNs@TiN-S electrode is 1097.8 mAh g⁻¹ and remains stable in the initial cycles. After 200 cycles, a reversible capacity of 812.6 mAh g⁻¹ is still retained, corresponding to 74% capacity retention of the original capacity and 0.13% decay rate per cycle, proving its relatively high specific capacitance and good long-term cycling stability. Better cycling performance of the HCNs@TiN-S electrode further confirms that the additional strong polar chemical interaction of TiN nanoparticles instead of only weak physical entrapment of carbon materials could effectively mitigate the shuttling effect of the polar LiPSs. Furthermore, compared with some similar sulfur cathodes that are summarized in Table S2, [15, 32, 44-46] the HCN@TiN-S electrode in this work also exhibits an attractive cycling stability.

4. Conclusions

In summary, to enhance the interaction with LiPSs and electrochemical performance of the cathode materials for Li-S batteries, we present an efficient strategy to bind TiN nano-particles to hollow carbon nanospheres by the sol-gel and microwave reduction nitridation methods. Through this way, we can quickly obtain well-crystallized TiN nano particles at a lower cost. Benefitting from the unique structural and outstanding functional behavior of the components, the as-prepared HCNs@TiN-S cathode material with 62.86 wt% sulfur content exhibits a high specific capacity of 1097.8 mAh g⁻¹ at 0.1C with excellent coulombic efficiency (≈98%), and retain a discharge capacity of 812.6 mAh g⁻¹ after 200 cycles at 0.1C. Testing results shows that, the HCNs@TiN composite can effectively alleviate the shuttle effects of polysulfide and enhance the utilization of sulfur compared with the HCNs without modification. It can be expected that other highly conductive metal nitrides could also act as electrode additives in Li-S batteries as shown in TiN in this work.
