Abstract

Multilayer thermal barrier coating (TBC) systems typically consist of three layers of materials: A thermal barrier top coat (TC), a thermally-grown oxide (TGO), and a bond coat (BC) in addition to the substrate. Local strain energy concentrations, called ‘pockets of energy concentration (PECs)’ in this work, often occur around the interface between the TGO and the BC. They have various causes, including local phase changes, and non-uniform creep and plastic relaxation. It is discovered that both PECs and buckling drive the spallation of a TBC in a new spallation mechanism. A PEC-based mechanical model is developed that describes, explains and predicts how blisters nucleate in a TBC under constant biaxial compressive residual stress, steadily and then unsteadily grow, and finally spall off. Two conditions are established for the occurrence of TBC spallation, which depend on the compressive residual strain energy density in the TC and the TGO, and the interface fracture toughness. Experimental validation of the model was performed using aircraft jet engine turbine blades with electron beam physical vapor deposition (EBPVD) TBCs. The predictions from the developed PEC-based mechanical model for the radii of spallation in the TBC are in a good agreement with experiment results.

Nomenclature

A, B, D	Extensional, coupling and bending stiffness
A_x	Amplitude of upward deflection of coating blister
b	Width of straight blisters
E	Young's modulus
G, G_I, G_{II}	Total, mode I and mode II energy release rates
G_{Ic}, G_{IIc}	Mode I and II interface fracture toughness
G_c	Interface fracture toughness
\bar{G}_c	Average fracture toughness over interface
M_{xB}, N_{xB}	Crack tip bending moment and effective force
M_x^R, N_x^R	Relaxation bending moment and effective force
h	Thickness of thermal barrier coating
R_B	Half-width of straight blisters; radius of circular blisters
U_a	Blister energy
U_s	Blister interface surface energy
U_0	Blister residual strain energy
w	Blister upward deflection
x, y	Lengthwise and widthwise coordinates of straight blisters
z	Out-of-plane coordinate
r, θ	Radial and circumferential coordinates of circular blisters
α	Buckling correction factor
ε^R, σ^R	Relaxation strain and stress due to bending deflection
ε^0, σ^0	Residual compressive strain and stress in thermal barrier coating
ν	Poisson's ratio
ξ	Measure of anisotropic coupling, $\xi = (AD - B^2)/(2AD)$
ψ	Ratio of interface mode II and I fracture toughness

Abbreviations

BC	Bond coat

EBPVD	Electron beam physical vapor deposition
ERR	Energy release rate
PEC	Pocket of energy concentration
TBC	Thermal barrier coating
TC	Top coat
TGO	Thermally grown oxide
YSZ	Yttria-stabilized zirconia

1 Introduction

Thermal barrier coating (TBC) material systems protect aero-engine components from the high and prolonged heat loads and improve engine durability and energy efficiency. A TBC material system is typically constructed from an yttria-stabilized zirconia (YSZ) ceramic top coat (TC) of low thermal conductivity, an MCrAlY overlay or diffusion bond coat (BC) that adheres the TC to an alloy substrate, and a thermally grown oxide (TGO) layer that forms at the interface between the TC and the BC at elevated temperature. Spallation failure, in which the TC detaches from the BC during service, has stimulated enormous research effort to understand the complex mechanisms driving the failure. Interested readers are referred to Refs. [1,2] for more information. The present work focuses on reporting a new mechanism of TBC spallation and on developing a mechanical model to describe, explain and predict the spallation behavior.

The TGO layer significantly reduces the adhesion toughness between the TC and the BC [3,4]. In addition, the large mismatch of coefficients of thermal expansion (CTEs) between the TGO and the BC results in a large compressive residual stress in the TGO layer during cooling. This very high compressive strain energy density in the TGO layer is therefore considered [2,5] to be a major cause of coating spallation. Moreover, local effects are also expected, with local strain energy concentrations around the TGO/BC interface. These local effects can be ascribed to various causes, including the existence of defects [6], non-uniform plastic and creep relaxation [7], the local roughness [8,9], the local phase changes [10], and local grain size and grain boundary changes [11]. The high compressive strain energy density and local effects together give rise to the aforementioned new mechanism of TBC spallation.

It is worth reviewing two recent studies [12,13] that are pertinent to the present work, in which the room-temperature spallation (i.e. spallation under constant biaxial compressive residual stress) of a single layer of α -alumina grown by oxidation on a Fe-Cr-Al alloy substrate is studied. The authors of these two studies, Wang, Harvey and Wang, reported that pockets of energy concentration (PECs) can exist in the form of pockets of tensile stress and shear stress in and around the interface between the TGO and the substrate. The origins of PECs were not determined in Refs. [12,13]; instead, the existence of PECs was taken as given and then the mechanical consequences for spallation behavior was predicted. Nevertheless, it was hypothesized that PECs can be caused by dynamic and non-uniform creep or plastic relaxation, or by thermal, chemical, or other processes. Based on this understanding of PECs, a mechanical model was developed which captured the entire process from nucleation to spallation and

which showed excellent agreement with the experimental measurements of circular blister spallation in Refs [14,15]. In contrast, the traditional buckling-driven approach, which assumes a pre-existing circular separation with a critical size slightly larger than the buckling size, cannot capture what is observed in these experiments [14,15]. Instead, the observed size of the α -alumina blister in nucleation and earlier stable growth stage is much smaller than the critical buckling size, which requests a significant amount of extra energy independent of the residual strain energy. It was therefore concluded that the PEC-based mechanical model [12,13] works very well while the traditional buckling-driven model does not.

The original contributions of this work are in (1) developing a PEC-based mechanical model to predict the spallation behavior of multilayer TBC material systems with variable material properties through the thickness of each layer under constant biaxial compressive residual stresses; and (2) conducting experimental tests to observe the spallation of TBCs under the same conditions. An additional aim of the work is to inform researchers in the field about this new mechanism of TBC spallation and to thereby promote wider research on the causes of PECs, resulting in design improvements for TBC material systems. Note that, again, the origins of PECs are not explicitly considered in this work, although the probable causes have been mentioned above. Determination of the causes of PECs is an enormous task that is much beyond the scope of the present work; however, regardless of their cause, it is still possible to establish the mechanical consequences of their existence.

The outline of the paper is as follows: PEC mechanical models are developed in Sections 2 and 3 for straight and circular blisters respectively. Both blister shapes have been observed in TBCs. Comparisons between model predictions and experimental results are given in Section 4. Conclusions are given in Section 5.

2 PEC-based mechanical model for straight blisters in multilayer TBCs

Figure 1 depicts a multilayer TBC with a straight blister of width $2R_b$, blister thickness h , length b , and height A_x . It is assumed that the blister consists of the TC and TGO, which are represented by the light and dark layer respectively. That is, the delamination is assumed to be on the TGO/BC interface, as is usually observed in experiments with EBPVD TBCs. Due to the assumed delamination location, in the following the TC and TGO are referred to collectively as the ‘top’, and the BC and substrate are referred to collectively as the ‘bottom’. Note that despite this assumption, the model developed here is generally applicable to other multilayer material systems and other crack locations.

Figure 1 A straight coating blister.

The axes in **Figure 1** show only the directions and not the origin. Following the convention of classical laminate theory, the origin of the z axis for the top is at its middle plane (that is, at the middle plane of the TC and TGO together). Likewise, the origin of the z axis for the bottom is at the middle plane of the substrate and BC together.

2.1 Residual stresses before delamination

Since the thickness of the bottom is much greater than the thickness of the top; therefore, the biaxial compressive stress in the bottom is approximately zero after cooling by $\Delta T_{\text{bot}}(z)$. Consequently, the total residual strain in the bottom consists only of thermal strain, which can be approximated as its average quantity over the thickness, as follows:

$$\varepsilon_{\text{bot}} = \int_{-h_{\text{bot}}/2}^{h_{\text{bot}}/2} C_{\text{bot}}(z) \Delta T_{\text{bot}}(z) dz / h_{\text{bot}}, \quad (1)$$

where h_{bot} and $C_{\text{bot}}(z)$ are the thickness and CTE of the bottom respectively.

Assuming that the top and bottom are perfectly bonded prior to delamination, the top will contract by the same amount as the bottom ε_{bot} as they are cooled from temperature $T_0(z)$ to T with $\Delta T(z) = T - T_0(z)$. The biaxial residual compressive stress $\sigma^0(z)$ in the top at temperature T is therefore

$$\sigma^0(z) = \frac{E(z)}{1-\nu(z)} [\varepsilon_{\text{bot}} - \varepsilon^T(z)], \quad (2)$$

where $\varepsilon^T(z) = C(z) \Delta T(z)$ represents the free thermal strain in the top due to the CTE $C(z)$ and cooling $\Delta T(z)$. The Young's modulus and Poisson's ratio of the top are $E(z)$ and $\nu(z)$ respectively; they are considered uniform in plane, but vary along the z axis.

In Eq. (2), $\varepsilon^T(z)$ can be expressed as the superposition of a uniform $\varepsilon^T(0)$, which is the value at the middle plane of the top, and a relative value $\Delta\varepsilon^T(z)$, that is,

$$\varepsilon^T(z) = C(z)\Delta T(z) = \varepsilon^T(0) + \Delta\varepsilon^T(z). \quad (3)$$

Now, substituting Eq. (3) into Eq. (2) gives

$$\sigma^0(z) = \frac{E(z)}{1-\nu(z)} \left\{ \varepsilon_{\text{bot}} - [\varepsilon^T(0) + \Delta\varepsilon^T(z)] \right\} = \frac{E(z)}{1-\nu(z)} \varepsilon^0(z), \quad (4)$$

where $\varepsilon^0(z)$ is the biaxial compressive residual strain in the top. For concise notation, let ε^0 denote $\varepsilon^0(0)$ or equivalently $\varepsilon_{\text{bot}} - \varepsilon^T(0)$. Now, the biaxial compressive residual stress $\sigma^0(z)$ in the top can be expressed in the following form:

$$\sigma^0(z) = \frac{E(z)}{1-\nu(z)} [\varepsilon^0 - \Delta\varepsilon^T(z)]. \quad (5)$$

Then, the resultant compressive residual force per unit width and bending moment per unit width are calculated as

$$N^0 = \int_{-h/2}^{h/2} \sigma^0(z) dz = A^* \varepsilon^0 - \Delta N^T \quad (6)$$

and

$$M^0 = \int_{-h/2}^{h/2} \sigma^0(z) z dz = B^* \varepsilon^0 - \Delta M^T, \quad (7)$$

where

$$A^* = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu(z)} dz \quad \text{and} \quad B^* = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu(z)} z dz, \quad (8)$$

and

$$\Delta N^T = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu(z)} \Delta\varepsilon^T(z) dz \quad \text{and} \quad \Delta M^T = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu(z)} \Delta\varepsilon^T(z) z dz. \quad (9)$$

Note that ΔN^T and ΔM^T in Eq. (9) are the resultant thermal force per unit width and thermal bending moment per unit width respectively due to $\Delta\varepsilon^T(z)$ in Eq. (3). Furthermore, Eqs. (6) and (7) show that the residual loads in the top are increased for negative $\Delta\varepsilon^T(z)$. This can be caused by TGO growth, sintering of the TC, etc.

2.2 Stresses after delamination

After delamination, the shape of the blister as shown in **Figure 1** is assumed to be sinusoidal [12,13], that is,

$$w(x) = \frac{A_x}{2} \left[1 + \cos\left(\frac{\pi x}{R_B}\right) \right], \quad (10)$$

from which the curvature κ of the upward bending is

$$\kappa = \frac{d^2 w}{dx^2} = -\frac{A_x \pi^2}{2R_B^2} \cos\left(\frac{\pi x}{R_B}\right). \quad (11)$$

Then the relaxation strains in the blister due to the upward bending, $\varepsilon_x^R(z)$ and $\varepsilon_y^R(z)$, based on classical plate theory, are

$$\varepsilon_x^R(z) = \varepsilon_x^R(0) - z \frac{d^2 w}{dx^2} \quad \text{and} \quad \varepsilon_y^R(z) = 0. \quad (12)$$

Note that the relaxation strain is plane strain, which results in $\varepsilon_y^R(z) = 0$ in Eq. (12). The quantity $\varepsilon_x^R(0)$ in Eq. (12) is the relaxation strain at the middle surface of the blister and can be calculated based on the conventional von Kármán geometric nonlinearity approach [13] as

$$\varepsilon_x^R(0) = \varepsilon_x^R = \frac{1}{2R_B} \int_0^{R_B} \left(\frac{dw}{dx} \right)^2 dx = \left(\frac{\pi A_x}{4R_B} \right)^2. \quad (13)$$

The relaxation stresses $\sigma_x^R(z)$ and $\sigma_y^R(z)$ are then calculated as

$$\sigma_x^R(z) = \frac{E(z)}{1-\nu^2(z)} \varepsilon_x^R(z) \quad \text{and} \quad \sigma_y^R(z) = \nu(z) \sigma_x^R(z), \quad (14)$$

which are positive in tension. The relaxation force per unit width and bending moment per unit width in the blister are calculated by using Eqs. (11) to (14) as

$$N_x^R = \int_{-h/2}^{h/2} \sigma_x^R(z) dz = A \varepsilon_x^R - B \kappa \quad (15)$$

and

$$M_x^R = \int_{-h/2}^{h/2} \sigma_x^R(z) z dz = B \varepsilon_x^R - D \kappa, \quad (16)$$

where the extensional stiffness A , coupling stiffness B and bending stiffness D are defined as

$$A = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu^2(z)} dz, \quad B = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu^2(z)} z dz \quad \text{and} \quad D = \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu^2(z)} z^2 dz. \quad (17)$$

The location $z = 0$ in Eq. (17) is at the middle surface of the blister. The axial force and bending moment in the blister are obtained by using Eqs. (6), (7), (15) and (16), which gives

$$N_x = N^0 - N_x^R = A^* \varepsilon^0 - \Delta N^T - A \varepsilon_x^R + B \kappa \quad (18)$$

and

$$M_x = M^0 - M_x^R = B^* \varepsilon^0 - \Delta M^T - B \varepsilon_x^R + D \kappa. \quad (19)$$

Note that stress relaxation only occurs in the blister due to upward bending deflection while the in-plane biaxial compressive residual stress $\sigma^0(z)$ in other parts of the multilayer TBC is unchanged.

2.3 Blister energy

The key consideration in the PEC-based approach [12,13] is to describe the ‘blister energy’ U_a , which is the net extra energy stored in the growing blister in comparison to the residual strain energy before blister development, U_0 . Note that ‘residual’ in ‘residual strain energy’ is used here to mean the strain energy accrued in the top layer after cooling to room temperature due to the mismatch of CTEs, instead of that remaining after fracture has occurred. The blister energy is provided by PECs and is expressed as

$$U_a = U_{SE} + U_s - U_0. \quad (20)$$

where U_{SE} is the total strain energy stored in the blister comprising the bending strain energy of the blister due to bending away from the substrate, and the in-plane strain energy of the blister due to the compressive residual stress in the film and stress relaxation in the blister from bending; and U_s is the surface energy of the delaminated surfaces of the blister. By studying the variation of the blister energy U_a with respect to the blister radius, the demand for PECs can be quantified, and furthermore, the blister growth behavior can be characterized.

The sum of the strain energy U_{SE} is given by

$$\begin{aligned}
U_{SE} &= \frac{b}{2} \int_{-R_B}^{R_B} \int_{-h/2}^{h/2} \left\{ \left[\sigma^0(z) - \sigma_x^R(z) \right] \left[\varepsilon^0(z) - \varepsilon_x^R(z) \right] \right. \\
&\quad \left. + \left[\sigma^0(z) - \sigma_y^R(z) \right] \left[\varepsilon^0(z) - \varepsilon_y^R(z) \right] \right\} dz dx \\
&= b \int_{-R_B}^{R_B} \left\{ \frac{A}{2} (\varepsilon_x^R)^2 - (B\kappa + A^* \varepsilon^0) \varepsilon_x^R + \left(A^* (\varepsilon^0)^2 + B^* \varepsilon^0 \kappa \right) + \frac{D\kappa^2}{2} \right. \\
&\quad \left. + \left[\Delta N^T (\varepsilon_x^R - 2\varepsilon^0) - \kappa \Delta M^T + 2\Delta u^T \right] \right\} dx \\
&= 2bR_B \left\{ \frac{A}{2} (\varepsilon_x^R)^2 + \left(\frac{D\pi^2}{R_B^2} - A^* \varepsilon^0 \right) \varepsilon_x^R + A^* (\varepsilon^0)^2 + \left[\Delta N^T (\varepsilon_x^R - 2\varepsilon^0) + 2\Delta u^T \right] \right\},
\end{aligned} \tag{21}$$

in which Δu^T represents the thermal strain energy density due to $\Delta \varepsilon^T(z)$ in Eq. (3), which is given by

$$\Delta u^T = \frac{1}{2} \int_{-h/2}^{h/2} \frac{E(z)}{1-\nu(z)} \left[\Delta \varepsilon^T(z) \right]^2 dz. \tag{22}$$

The surface energy due to the interface fracture U_s in Eq. (20) is

$$U_s = 2bR_B \bar{G}_c, \tag{23}$$

where \bar{G}_c is the average fracture toughness over the interface. Note that U_s includes both fracture surfaces.

The residual strain energy before delamination U_0 in Eq. (20) is calculated using Eqs. (5) and (9) as

$$U_0 = \frac{b}{2} \int_{-R_B}^{R_B} \int_{-h/2}^{h/2} \left[2\sigma^0(z) \varepsilon^0(z) \right] dz dx = 2bR_B \left[A^* (\varepsilon^0)^2 - 2\varepsilon^0 \Delta N^T + 2\Delta u^T \right]. \tag{24}$$

Substituting the energy terms above, along with Eq. (6), into Eq. (20) leads to the blister energy U_a as

$$U_a = 2bR_B \left\{ \frac{A}{2} (\varepsilon_x^R)^2 + \left(\frac{D\pi^2}{R_B^2} - N^0 \right) \varepsilon_x^R + \bar{G}_c \right\}. \tag{25}$$

2.4 Mixed-mode interface fracture based on classical plate partition theory

2.4.1 Nucleation and stable growth

The task is now to study the interface fracture behavior during blister development by invoking different partition theories [16–21] of energy release rate (ERR) for mixed-mode fracture. The blister grows if the ERR equals or exceeds the interface fracture toughness. The

measured residual stress at the blister tips in Ref. [14] highlights that the relaxation stress is approximately zero. Therefore, the axial force and bending moment at the blister tip are, respectively,

$$N_{xB} = \left[-\left(N^0 - N_x^R \right) + N^0 \right] \Big|_{x=R_B} = 0 \quad (26)$$

and

$$\begin{aligned} M_{xB} &= \left[-M^0 + \left(M^0 - M_x^R \right) \right] \Big|_{x=R_B} = -M_{x=R_B}^R \\ &= -\left(B\varepsilon_x^R - D\kappa \right) \Big|_{x=R_B} = \left(-B + \frac{8}{A_x} D \right) \varepsilon_x^R, \end{aligned} \quad (27)$$

in which, from Eqs. (11) and (13), the deflection curvature κ at the blister tip is

$$\kappa \Big|_{x=R_B} = \frac{d^2 w}{dx^2} \Big|_{x=R_B} = \frac{A_x \pi^2}{2R_B^2} = \frac{8}{A_x} \varepsilon_x^R. \quad (28)$$

Following from Ref. [18], the total ERR is

$$G = \frac{AM_{xB}^2}{2(AD - B^2)}. \quad (29)$$

Based on the classical plate partition theory or Euler beam partition theory [16–18], the pure mode-I and mode-II ERRs are

$$G_{IE} = \frac{AM_{xB}^2}{2(AD - B^2)} \quad \text{and} \quad G_{IIE} = G - G_{IE} = 0, \quad (30)$$

where the subscript ‘E’ denotes classical plate or Euler beam partition theory. Eqs. (29) and (30) suggest the delamination is pure mode-I fracture, that is, $G_{cE} = G_{lc}$ where the subscript ‘c’ denotes the critical ERR. The linear fracture propagation criterion is used to determine whether the crack advances [13,22,23], that is, the condition for fracture propagation is

$$G = G_c = \frac{\psi G_{lc}}{(G_I/G)(\psi - 1) + 1}, \quad (31)$$

where $\psi = G_{IIC}/G_{lc}$.

Substituting Eqs. (29) and (30) into Eq. (31), and using Eqs. (13) and (27), leads to

$$A_x^2 \left[1 - \frac{BA_x}{8D} \right]^2 = \frac{(AD - B^2)}{AD} \frac{8G_{ce}}{\pi^4 D} R_B^4. \quad (32)$$

According to classical laminate theory, $(AD - B^2)$ is always positive. This also satisfies the requirement for ERR in Eq. (29) to be positive. Then, A_x is obtained from Eq. (32) as

$$(A_x)_{GRE} = \frac{4D}{B} \left[1 - \left(1 - R_B^2 \frac{2B}{D\pi^2} \sqrt{\frac{G_{ce}\xi}{D}} \right)^{1/2} \right], \quad (33)$$

where $\xi = (AD - B^2)/(2AD)$ and the subscript ‘GR’ denotes a quantity during growth. For a multilayer TBC, $\xi \leq 1/2$, and for an isotropic blister layer, $\xi = 1/2$. Furthermore, it is easily shown that the second term inside the square brackets of Eq. (32) is generally much smaller than 1 and negligible. The corresponding A_x is

$$(A_x^2)_{GRE} = \xi \frac{16G_{ce}}{\pi^4 D} (R_B^4)_{GRE}. \quad (34)$$

The mid-surface relaxation strain during growth is obtained by substituting Eq. (34) into Eq. (13), giving

$$(\varepsilon_x^R)_{GRE} = \xi \frac{G_{ce} (R_B^2)_{GRE}}{\pi^2 D}. \quad (35)$$

Then, the blister energy during growth is then obtained by substituting Eq. (35) into Eq. (25), and noting that $\bar{G}_c = G_{ce}$, as shown by Eqs. (30) and (31), giving

$$(U_a)_{GRE} = 2b(R_B)_{GRE} \left\{ \frac{A}{2} \left(\frac{\xi G_{ce}}{\pi^2 D} \right)^2 (R_B^4)_{GRE} - N^0 \frac{\xi G_{ce}}{\pi^2 D} (R_B^2)_{GRE} + G_{ce} (1 + \xi) \right\}. \quad (36)$$

Note that $(U_a)_{GRE}$ in Eq. (36) is for delamination on the TGO/BC interface only without any consideration for ridge cracks. It will, however, be seen in Section 4.2 that the developed mechanical model can still give good agreement with test results even if ridge cracks appear. This is may be because the surface energy associated with ridge-cracks is generally small due to the relatively small crack area in comparison to that associated with delamination. Moreover, since ridge cracks ‘consume’ a small amount of blister energy, the measured spallation radius is expected to be slightly smaller than the predicted one, which will be observed in Section 4.2.

During blister nucleation, R_B is very small and the higher-order R_B terms in Eq. (36) can be neglected, giving

$$(U_a)_{\text{NUE}} = 2b(R_B)_{\text{NUE}} G_{\text{ce}} (1 + \xi), \quad (37)$$

where ‘NU’ denotes the nucleation of a blister. This is the blister nucleation energy, which must be supplied by some energy source if a blister is to nucleate. According to the PECs hypothesis, this energy source is PECs.

Eq. (37) shows that the blister nucleation energy solely depends on the mechanical properties, namely, interface fracture toughness, Young’s modulus and Poisson’s ratio, and their through-thickness variations. Taking EBPVD TBCs as an example, the TC has a dense layer near to the TGO, a coarse layer near to the TC surface, and sintering on the TC surface. Since $\xi \leq 1/2$ for a multilayer TBC, as shown above, then $(1 + \xi)$ in Eq. (37) has a maximum value of 1.5, which is when the bending-stretching coupling stiffness B is zero. TGO growth increases the value of B and thus decreases the nucleation energy.

2.4.2 Initiation of unstable growth

After nucleation, a blister initially grows steadily and slowly, with PECs supplying the required energy for blister growth, as described by Eq. (36). If the required energy is not available, then the blister cannot grow further and stalls. Assuming a sufficient supply of energy for continued blister growth, then when the blister width reaches a certain critical value, the blister then grows unstably. Following Refs. [12,13] for a monolayer film, based on the buckling condition of a thin plate, the condition for unstable growth of a straight blister is

$$N^0 - \bar{N}_x^R = \frac{(\alpha\pi)^2 D}{R_B^2}, \quad (38)$$

where, from Eqs. (15) and (11), $\bar{N}_x^R = \int_0^{R_B} N_x^R dx / R_B = A(\varepsilon_x^R)_{\text{GRE}}$, which represents the average axial relaxation force. The range of α is $0.5 \leq \alpha \leq 1.0$ and the two limits correspond to the simply-supported and clamped edge conditions respectively. Refs. [12,13] have demonstrated that $\alpha = 0.75$ is a good approximation for a single layer blister with a brittle interface.

The blister half-width for the initiation of unstable growth $(R_B)_{\text{UGE}}$ can be obtained from the following by combining Eqs. (35) and (38) as

$$(R_B^2)_{\text{UGE}} = \frac{\pi^2 D \varphi_E^0}{2\xi A} \left[1 - \left(1 - \frac{2\alpha^2 \xi}{\Omega_E} \right)^{1/2} \right], \quad (39)$$

where ‘UG’ denotes the unstable growth of the blister, and

$$\Omega_E = \frac{N^0}{2A} \varphi_E^0 = \frac{(N^0)^2}{2AG_{ce}} \quad \text{and} \quad \varphi_E^0 = \frac{N^0}{G_{ce}}. \quad (40)$$

Note that Ω represents the ratio between the in-plane strain energy per unit width and the interface adhesion toughness. The Ω ratio plays a key role in blister development.

From Eq. (39), unstable growth only occurs if $\Omega_E \geq 2\alpha^2\xi$. Since $\xi \leq 1/2$, the maximum possible value of $2\alpha^2\xi$ is α^2 , which is for an isotropic blister. TGO growth and TC sintering make $\Delta\varepsilon^T(z)$ in Eq. (3) increasingly negative, and consequently increase Ω_E by increasing N^0 in Eq. (6). Furthermore, they simultaneously decrease $2\alpha^2\xi$ because of the increased stretching-bending coupling of the TBC. When $\Omega_E \square 2\alpha^2\xi$, binomial expansion of the square brackets in Eq. (39) leads to

$$(R_B^2)_{UGE} = \frac{(a\pi)^2 D}{N^0}. \quad (41)$$

This reveals that TGO growth and TC sintering promote unstable growth by increasing the residual loads and decreasing $(R_B^2)_{UGE}$ in Eq. (41). Note that for uniform material properties through the blister thickness, Eq. (41) reduces to the same form given in Refs. [12,13].

When $\Omega_E \square 2\alpha^2\xi$, the blister height, mid-surface relaxation strain and the blister energy at the initiation of unstable growth are derived by substituting Eq. (41) into Eqs. (34), (35) and (36) respectively, giving

$$(A_x^2)_{UGE} = \frac{8\xi D\alpha^4}{A\Omega_E}, \quad (42)$$

$$(\varepsilon_x^R)_{UGE} = \frac{\xi\alpha^2}{\varphi_E^0} \quad (43)$$

and

$$\begin{aligned} (U_a)_{UGE} &= 2b(R_B)_{UGE} G_{ce} \left[\frac{\xi^2\alpha^4}{4\Omega_E} + \xi(1-\alpha^2) + 1 \right] \\ &\approx 2b(R_B)_{UGE} G_{ce} \left[\xi(1-\alpha^2) + 1 \right]. \end{aligned} \quad (44)$$

2.4.3 Maximum blister energy and unstable growth

Based on Eq. (36), the blister energy reaches its maximum value at

$$(R_B^2)_{\text{MUE}} = \frac{3D\pi^2\phi_E^0}{5\xi A} \left[1 - \left(1 - \frac{5(1+\xi)}{9\Omega_E} \right)^{1/2} \right], \quad (45)$$

where ‘MU’ denotes the maximum blister energy. Note that $(R_B^2)_{\text{MUE}}$ exists only if $\Omega_E \geq 5(1+\xi)/9$. The maximum possible value of $5(1+\xi)/9$ is $5/6$, which is for an isotropic blister with $\xi = 1/2$. Without considering other effects such as creep or plastic relaxation, TGO growth and TC sintering act to increase Ω_E by increasing N^0 in Eq. (6), and simultaneously decrease $5(1+\xi)/9$. When $\Omega_E \leq 5(1+\xi)/9$, binomial expansion of the square brackets in Eq. (45) leads to

$$(R_B^2)_{\text{MUE}} = \frac{(1+\xi)\pi^2 D}{3N^0 \xi}. \quad (46)$$

When $\Omega_E \leq 5(1+\xi)/9$, the blister height, mid-surface relaxation strain and the blister energy are obtained by substituting Eq. (46) into Eqs. (34), (35) and (36) respectively, giving

$$(A_x^2)_{\text{MUE}} = \frac{8D(1+\xi)^2}{9A\Omega_E \xi}, \quad (47)$$

$$(\varepsilon_x^R)_{\text{MUE}} = \frac{(1+\xi)}{3\phi_E^0} \quad (48)$$

and

$$(U_a)_{\text{MUE}} = 2b(R_B)_{\text{MUE}} G_{\text{ce}} \left\{ \frac{(1+\xi)^2}{36\Omega_E} + \frac{2(1+\xi)}{3} \right\} \approx \frac{4}{3} b(R_B)_{\text{MUE}} G_{\text{ce}} (1+\xi). \quad (49)$$

Since the maximum blister energy radius $(R_B)_{\text{MUE}}$ in Eq. (46) is greater than unstable growth radius $(R_B)_{\text{UGE}}$ in Eq. (39), after the initiation of unstable growth, the blister energy continues to increase up to the blister energy capacity $(U_a)_{\text{MUE}}$. Since the blister energy U_a is increasing up to this point, an energy source is still required despite the growth being unstable. As before, according to the hypothesis of PECs, PECs are the energy source that supplies this blister energy. If PECs cannot provide the required energy, then the blister cannot grow further and stalls.

2.4.4 Spallation

After the blister energy has reached its maximum value of $(U_a)_{MUE}$, it then decreases with further blister growth, and no more energy is needed from PECs. The blister now has enough energy stored in itself to continue propagating, and it is therefore both fast and unstable as the blister energy is converted into kinetic energy. If the blister energy reduces to zero and the kinetic energy of the blister due to the fast unstable growth is large enough to break the blister edges, then the blister will spall off from the substrate. From Eq. (36), the blister half-width at spallation $(R_B)_{SPE}$ is obtained from

$$(R_B^2)_{SPE} = \frac{D\pi^2\phi_E^0}{\xi A} \left[1 - \left(1 - \frac{(1+\xi)}{\Omega_E} \right)^{1/2} \right]. \quad (50)$$

Note that the negative square root in Eq. (50) is chosen to get the smaller value of $(R_B^2)_{SPE}$. It is seen that no solutions for $(R_B^2)_{SPE}$ exist if $\Omega_E < (1+\xi)$, and so spallation cannot occur if this condition is satisfied. When $\Omega_E \geq (1+\xi)$, binomial expansion of the square brackets in Eq. (50) leads to

$$(R_B^2)_{SPE} = \frac{\pi^2 D(1+\xi)}{\xi N^0}. \quad (51)$$

When $\Omega_E \geq (1+\xi)$, the blister height and mid-surface relaxation strain are obtained by substituting Eq. (46) into Eqs. (34) and (35) respectively, giving

$$(A_x^2)_{SPE} = \frac{8D(1+\xi)^2}{A\xi\Omega_E} \quad (52)$$

and

$$(\varepsilon_x^R)_{SPE} = \phi_E^0(1+\xi). \quad (53)$$

Two conditions are derived in the above for the spallation of TBCs to occur: (1) From Eq. (49), PECs must be able to supply sufficient energy to take the blister energy to $(U_a)_{MUE}$. After this point, the blister has stored enough energy in itself to continue propagating with no further energy requirement. (2) From Eq. (50), Ω_E must be $\Omega_E \geq (1+\xi)$. These two conditions provide valuable guidance for TBC design and optimisation to avoid spallation failure.

Condition 1 partly relates to the prevalence of PECs and the availability of energy for blister development, but this depends on the precise cause of PECs, which is beyond the scope of this work. The maximum blister energy $(U_a)_{\text{MUE}}$, however, can be increased to delay condition 1 being satisfied. From Eqs. (46) and (49), this could be achieved by decreasing N^0 —by decreasing ε^0 or by increasing N^T via $\Delta\varepsilon^T(z)$ as per Eq. (6)—or by increasing G_{cE} . Note that ξ has a limited range so has a relatively minor effect. Condition 2 requires decreasing Ω_E , which, as the ratio of in-plane strain energy density per unit width to interface adhesion toughness, could be achieved in the same ways as for condition 1.

Practically, increased lifetime of EBPVD TBCs could therefore be achieved by: (1) Reducing the thickness of the dense-layer at the bottom of the TC. (2) Reducing the growth rate of the TGO. (3) Suppressing TC sintering. (4) Reducing the temperature difference across the coating. (5) Reducing mismatch of CTEs between the blister and the BC.

2.5 Mixed-mode interface fracture based on first-order shear-deformable plate partition theory and 2D elasticity partition theory

The mixity of a mixed-mode interface fracture depends on the partition theory. In this section, the PEC-based mechanical model developed in Section 2.4 using classical plate partition theory is adjusted for first-order shear-deformable plate partition theory (or equivalently, Timoshenko beam partition theory) [16,17,22–24] and for 2D elasticity partition theory [19,20,22,25]. The parameters G_{cE} , Ω_E and φ_E^0 in the above need to be replaced by G_{cT} , Ω_T , and φ_T^0 respectively for first-order shear-deformable plate partition theory, and by G_{c2D} , Ω_{2D} and φ_{2D}^0 respectively 2D elasticity partition theory.

The ERRs based on first-order shear-deformable plate partition theory are

$$G_{\text{IT}} = \frac{2M_{\text{xB}}^2}{(Ah^2 + 4Bh + 4D)} \quad \text{and} \quad G_{\text{IIT}} = G - G_{\text{IT}}. \quad (54)$$

From Eqs. (29) and (54), the fracture mode mixity is constant at $G_{\text{IT}}/G = 4(AD - B^2)/[A(Ah^2 + 4Bh + 4D)] = 1/\psi_{\text{IT}}$. Substituting $G_{\text{IT}}/G = 1/\psi_{\text{IT}}$ into Eq. (31) gives

$$\lambda_{\text{T}} = \frac{G_{\text{cT}}}{G_{\text{lc}}} = \frac{\psi\psi_{\text{IT}}}{\psi + \psi_{\text{IT}} - 1}. \quad (55)$$

Therefore the relationship between the critical ERR from first-order plate partition theory and that from classical plate partition theory is

$$G_{cT} = \lambda_T G_{Ic} = \lambda_T G_{cE}. \quad (56)$$

Now Ω_T and φ_T^0 are obtained by substituting Eq. (56) into Eq. (40), giving

$$\Omega_T = \frac{N^0}{2A} \varphi_T^0 = \frac{(N^0)^2}{2AG_{cT}} = \frac{\Omega_E}{\lambda_T} \quad \text{and} \quad \varphi_T^0 = \frac{N^0}{G_{cT}}. \quad (57)$$

Similarly, the ERRs based on 2D elasticity partition theory are

$$G_{I2D} = 0.6227 \frac{6M_{xB}^2}{Ah^2} \quad \text{and} \quad G_{II2D} = G - G_{I2D}. \quad (58)$$

The fracture mode mixity is constant at $G_{I2D}/G_{2D} = 0.6227 \left[12(AD - B^2) / (A^2 h^2) \right] = 1/\psi_{I2D}$.

The quantities G_{c2D} , Ω_{2D} and φ_{2D}^0 are determined in the same way as above, with λ_{2D} obtained by replacing ψ_{IT} with ψ_{I2D} in Eq. (55), giving

$$G_{c2D} = \lambda_{2D} G_{Ic} = \lambda_{2D} G_{cE}, \quad (59)$$

$$\Omega_{2D} = \frac{N^0}{2A} \varphi_{2D}^0 = \frac{(N^0)^2}{2AG_{c2D}} = \frac{\Omega_E}{\lambda_{2D}} \quad \text{and} \quad \varphi_{2D}^0 = \frac{N^0}{G_{c2D}}. \quad (60)$$

3 PEC-based mechanical model for circular blisters in multilayer TBCs

The PEC-based mechanical model for the circular blisters is similar to the model for straight blisters, described in Section 2; therefore, only the key differences are recorded in this section. **Figure 2** shows a multilayer circular blister of diameter $2R_b$, blister thickness h , and height A_r . The model is developed in polar coordinates, and so the x coordinate in Section 2 is swapped to the r coordinate where appropriate.

Figure 2 A circular coating blister.

The circular blister shape is assumed to be axisymmetric and sinusoidal [12,13], obeying

$$w(r) = \frac{A_r}{2} \left[1 + \cos\left(\frac{\pi r}{R_B}\right) \right]. \quad (61)$$

Based on the assumed blister shape, the blister energy is

$$U_a = \pi R_B^2 \left\{ \frac{A}{2} (\varepsilon_x^R)^2 + \left(\frac{D\pi^2}{R_B^2} - N^0 \right) \varepsilon_x^R + \bar{G}_c \right\}. \quad (62)$$

Note the similarity between the blister energy in Eq. (62) for circular blisters and that for straight blisters in Eq. (25).

The total ERR and its mixity for a circular blister, based on classical plate partition theory [16–18], are identical to those for straight blisters, as given in Eqs. (29) and (30) respectively. The linear fracture propagation criterion in Eq. (31) is still used to determine crack propagation. There are no changes to $(A_r)_{GRE}$ and $(\varepsilon_r^R)_{GRE}$, as given in Eqs (34) and (35) respectively.

Based on these expressions, the blister energy of a circular blister during growth is

$$(U_a)_{GRE} = \pi (R_B^2)_{GRE} \left\{ \frac{A}{2} \left(\frac{\xi G_{ce}}{\pi^2 D} \right)^2 (R_B^4)_{GRE} - N^0 \frac{\xi G_{ce}}{\pi^2 D} (R_B^2)_{GRE} + G_{ce} (1 + \xi) \right\}, \quad (63)$$

and the nucleation energy is

$$(U_a)_{NUE} = \pi (R_B^2)_{NUE} G_{ce} (1 + \xi). \quad (64)$$

For the initiation of unstable growth of a circular blister, there are no changes to $(R_B)_{UGE}$, $(A_r)_{UGE}$ and $(\varepsilon_r^R)_{UGE}$, as given in Eqs. (39), and (41) to (43) respectively. Note, however, that the range of α now becomes $0.652 \leq \alpha \leq 1.220$ where the two limits correspond to the simply-

supported and clamped edge conditions respectively. It has been shown that $\alpha = 0.936$ is a good approximation [12,13]. Based on these expressions together with Eq. (63), the blister energy of a circular blister at the initiation of unstable growth if $\Omega_E \leq 2\alpha^2\xi$ is

$$\begin{aligned} (U_a)_{UGE} &= \pi (R_B^2)_{UGE} G_{ce} \left[\frac{\xi^2 \alpha^4}{4\Omega_E} + \xi(1-\alpha^2) + 1 \right] \\ &\approx \pi (R_B^2)_{UGE} G_{ce} [\xi(1-\alpha^2) + 1]. \end{aligned} \quad (65)$$

The blister energy of a circular blister reaches its maximum value at

$$(R_B^2)_{MUE} = \frac{2D\pi^2\varphi_E^0}{3\xi A} \left[1 - \left(1 - \frac{3(1+\xi)}{4\Omega_E} \right)^{1/2} \right]. \quad (66)$$

There are no solutions for $(R_B^2)_{MUE}$ if $\Omega_E < 3(1+\xi)/4$. When $\Omega_E \geq 3(1+\xi)/4$, binomial expansion of the square brackets in Eq. (66) leads to

$$(R_B^2)_{MUE} = \frac{D\pi^2(1+\xi)}{2\xi N^0}. \quad (67)$$

The blister height, mid-surface axial relaxation strain and the maximum blister energy are obtained by substituting Eq. (67) into Eqs. (34), (35) and (36) respectively, giving

$$(A_x^2)_{MUE} = \frac{2D(1+\xi)^2}{A\xi\Omega_E}, \quad (68)$$

$$(\varepsilon_x^R)_{MUE} = \frac{(1+\xi)}{2\varphi_E^0} \quad (69)$$

and

$$(U_a)_{MUE} = \pi (R_B^2)_{MUE} G_{ce} \left\{ \frac{(1+\xi)^2}{16\Omega_E} + \frac{(1+\xi)}{2} \right\} \approx \frac{1}{2} \pi (R_B^2)_{MUE} G_{ce} (1+\xi). \quad (70)$$

For the spallation of a circular blister, there are no changes to Eqs. (50) to (53). The mechanical model given above, based on classical plate partition theory, can also be adjusted for first-order shear-deformable plate partition theory and for 2D elasticity partition theory by changing the relevant parameters, as described in Section 2.5. There is no change to those parameters for circular blisters.

4 Experimental validation

In this section, the developed PEC-based mechanical model for multilayer material systems is verified first against radius measurements of alumina scale spallation [26], and then against radius measurements of EBPVD TBC spallation [27]. Note that all spallation happens having reached room temperature, that is, under constant biaxial compressive residual stress.

4.1 Alumina scale spallation

The relevant experimental details of the alumina spallation tests are recorded here from Refs. [26]. The specimens were 25.4 mm diameter discs of commercial FeCrAlY alloy (Fe–22Cr–5Al–0.1Y–0.3Si–0.2Mn–0.1Zr–0.02C in wt%), with thicknesses of 0.477 mm, 1.394 mm, 3.349 mm and 7.608 mm, polished to a 0.25- μm finish on both sides. The specimens were oxidized in a chamber furnace at the isothermal temperature of 1200 °C, following heating at 3 °C min⁻¹, to produce a uniform flat alumina scale, adhered to the substrate surface. The 4.5 μm -thick alumina films were generated after being oxidized for 25 h, and the specimens were cooled to room temperature at various cooling rates (1, 5, 10, 30 and 100 °C min⁻¹), as indicated in **Table 1**. Compressive residual stress was generated in the scale during cooling and became constant upon reaching room temperature. The residual stress in the scale was measured using photo-stimulated luminescence spectroscopy, and the values for each group are additionally recoded in **Table 1**. The spallation behavior of the alumina layer was monitored using an optical microscope as well as scanning electron microscopy (SEM). When the cooling rate was 1 or 100 °C min⁻¹, spallation was not observed but blisters were evident. For the intermediate cooling rates of 5, 10 and 30 °C min⁻¹, spallation occurred significantly.

Table 1 Values of Ω based on the E, T and 2D partition theories for different experimental samples.

Cooling rate, substrate thickness	h (μm)	σ_0 (GPa)	Ω		
			E	T	2D
30 °C min ⁻¹ , 0.477 mm	4.5	3.023	5.6037	2.2415	3.9123
30 °C min ⁻¹ , 1.394 mm	4.5	4.142	10.5200	4.2080	7.3448
10 °C min ⁻¹ , 1.394 mm	4.5	3.845	9.0654	3.6262	6.3293
5 °C min ⁻¹ , 1.394 mm	4.5	3.759	8.6644	3.4658	6.0493
30 °C min ⁻¹ , 3.349 mm	4.5	4.468	12.2411	4.8965	8.5465
30 °C min ⁻¹ , 7.608 mm	4.5	4.947	15.0065	6.0026	10.4772

The Young's modulus of the alumina scale is $E_{\text{TGO}} = 400$ GPa and the Poisson's ratio is $\nu_{\text{TGO}} = 0.25$ [7,28]. The mode-I fracture toughness of the interface between the scale and the substrate is $G_{\text{ic}} = 8.6$ J m⁻² [4] and the fracture toughness ratio ψ is 5 [29]. Since the alumina scale is isotropic, $\Delta\epsilon^T(z)$ in Eq. (3) equals zero, and the fracture toughness G_c , based on classical plate partition theory, first-order shear-deformable plate partition theory, and 2D elasticity partition theory, is calculated as 8.60 J m⁻², 21.50 J m⁻² and 12.32 J m⁻² respectively. The values of Ω for the various samples are calculated and summarized in **Table 1**. It is seen that all values of Ω are more than $3/2$ which is required by Eq. (51). Using the mechanical model for circular blisters with $\alpha = 0.936$, the radii for initiation of unstable growth and spallation are predicted and compared with experimental measurements in **Table 2**, where 'E', 'T' and '2D' denote classical plate partition theory, first-order shear-deformable plate partition theory, and 2D elasticity partition theory respectively. Note that the blisters were "circular" or "near-circular" [26] and the average diameter was measured based on ten random images from each sample.

From **Table 2**, it is seen that spallation radii predicted by the mechanical model using each of the three partition theories are all in excellent agreement with the experimental measurements. Since $\Omega \geq 3/2$, the approximate Eqs. (41) and (51) are appropriate and also work very well. No radius measurements at the initiation of unstable growth are available. Overall, the accuracy of the mechanical model in predicting spallation radius provides strong support for the hypothesis that spallation is driven by both PECs and buckling.

Table 2 Radii for initiation of unstable growth and spallation and comparisons with experimental measurements (spallation only).

Cooling rate, substrate thickness	R_B at initiation of unstable growth (μm)				R_B at spallation (μm)				
	Eq. (39)		Eq. (41)		Eq. (50)			Eq. (51)	
	E	T	2D	All	E	T	2D	All	Test data
30 °C min ⁻¹ , 0.477 mm	46.33	48.10	46.80	45.38	87.18	94.63	88.88	83.98	89.70±4.00
30 °C min ⁻¹ , 1.394 mm	39.19	39.88	39.38	38.77	73.11	75.58	73.76	71.74	74.29±4.00
10 °C min ⁻¹ , 1.394 mm	40.75	41.60	40.98	40.24	76.12	79.25	76.93	74.46	76.60±4.00
5 °C min ⁻¹ , 1.394 mm	41.23	42.15	41.48	40.70	77.08	80.44	77.94	75.31	76.60±4.00
30 °C min ⁻¹ , 3.349 mm	37.67	38.24	37.83	37.33	70.19	72.16	70.72	69.07	71.66±4.00
30 °C min ⁻¹ , 7.608 mm	35.74	36.17	35.86	35.47	66.5	67.96	66.9	65.65	67.20±4.00

Although it is not the objective of this work to determine the origin of PECs, the experimental observations presented in Refs. [26] suggest the following possible sources of PECs in the case of these FeCrAlY alloy/alumina tests: (1) Imprints of alumina grains on the substrate, which make rough and wrinkled interfaces; (2) dislocations of grain boundaries at interfaces; (3) plastic deformation; and (4) Chromium carbide segregation.

4.2 EBPVD coating spallation

In the third comparison, the mechanical model for multilayer material systems is verified by applying it to the problem of EBPVD TBC spallation after cooling to room temperature. Whole new turbine blades were used for testing, which were coated with an EBPVD TBC comprising an YSZ ceramic TC layer, a TGO layer, and a Pt-diffused BC layer on the single crystal CMSX-4 Ni-based superalloy substrate. The thickness of the TC is 138 μm , and its Young's modulus through-thickness variation is described by

$$\frac{E_{\text{YSZ}}}{[\text{GPa}]} = -8 \times 10^{-5} \frac{z_{\text{YSZ}}^3}{[\mu\text{m}^3]} + 0.0192 \frac{z_{\text{YSZ}}^2}{[\mu\text{m}^2]} - 1.5812 \frac{z_{\text{YSZ}}}{[\mu\text{m}]} + 85.5850 \quad (71)$$

where $z_{\text{YSZ}} = 0$ is at the bottom of the TC and is positive upward, and the Poisson's ratio is $\nu_{\text{YSZ}} = 0.2$ [28]. This through-thickness variation of Young's modulus is based on a polynomial fit to experimental results in Ref. [30] from testing the same TBC system after 120 h of isothermal heating at 1150 °C. These results [30] and the polynomial fit are shown in **Figure 3**.

Figure 3 Through-thickness variation of Young's modulus in the YSZ ceramic TC layer after 120 h of isothermal heating at 1150 °C [30].

The thickness of the TGO is considered thin enough at 5 μm to assume an average Young's modulus of $E_{\text{TGO}} = 400$ GPa with a Poisson's ratio of $\nu_{\text{TGO}} = 0.25$ [7,28]. Scanning electron microscope images, such as that in **Figure 4**, have identified that coating spallation of this TBC system occurs at the interface between the TGO and the BC. This also agrees with Refs. [2,31,32]. The blister layer is therefore a bi-layer consisting of the TC and the TGO. Note that although **Figure 4** shows a wavy interface, its amplitude in comparison to the thickness of the combined TC and TGO (as the top layer in the developed mechanical model) is negligible and the flat-interface model is considered valid. **Figure 4** is of a coupon sample cut from the pressure side of the blade. It was isothermally heated at 1135 °C for 50 h and then naturally cooled to room temperature in the lab environment. The sample was embedded in epoxy and the cross-section was polished to a 1- μm surface finish for observation.

Figure 4 A representative scanning electron microscope image of a TBC coupon sample showing cracking between the TGO and the BC.

The stiffness per width of the top layer (i.e. the blister layer, comprising the TC and TGO) is given by Eq. (17): Extensional stiffness $A = 14004.911 \text{ N mm}^{-1}$, coupling stiffness $B = -117.521 \text{ N}$ and bending stiffness $D = 29.076 \text{ N mm}$. Eq. (8) then gives $A^* = 16912.560 \text{ N mm}^{-1}$ and $B^* = -148.386 \text{ N}$. The typical CTE mismatch between the top layer and the bottom layer (i.e. the BC and the substrate together) is $4 \text{ ppm } ^\circ\text{C}^{-1}$ [4]. The mode-I fracture toughness at the interface between the TGO and BC is 8.4 J m^{-2} [4] and the fracture toughness ratio ψ is 5 [29].

Specimens were isothermally oxidized at $1135 \text{ }^\circ\text{C}$ and cooled to room temperature at $25 \text{ }^\circ\text{C}$ in the laboratory environment. For this $1110 \text{ }^\circ\text{C}$ of cooling, the biaxial compressive residual strain is calculated as 0.44% . For the specific specimen described in this section, there were seven heating-cooling cycles (reaching a total 220 h of heating) until the convex surface spalled. The first heating period was for 100 h, which then continued with a further six heating-cooling cycles of 20 h. No spallation failure occurred during cooling, but after the seventh heating-cooling cycle, the convex surface of the blade spalled off shortly after reaching room temperature (i.e. at a constant biaxial compressive residual stress).

Note that eight new specimens in total were tested with slight variations in the procedure in order to establish the most effective technique. It was very challenging to record images over the whole curved surface of the blade, and over the whole duration of cooling and dwelling at room temperature. The results described here are for the single specimen which displayed both circular and straight blisters (and can therefore be modelled theoretically), and for which the whole spallation process was clearly captured. Qualitatively, however, all the specimens

displayed the same spallation behavior, even though accurate measurements are not available for the reasons stated above.

Figure 5 shows a sequence of optical and processed images from Ref. [27], illustrating the nucleation, growth, branching, and spallation of a circular blister on the convex surface. Timing started when the specimen was removed from the furnace. The recording speed is 30 frames per second. The blister is visible due to the scattering of light from the surface (the top of each subfigure in **Figure 5**); however, to make the blister more prominent for easier blister radius measurements and for clearer presentation here, image (a) was subtracted from images (b) to (h) in post-processing to reveal just the difference between these images and image (a) (the bottom of each subfigure in **Figure 5**). The uncertainty in measuring the blister radius from these images is 0.1 mm.

Figure 5 Sequence of optical and processed images [27] showing the nucleation (b), stable growth (b-c) and unstable growth (c-g), branching (e-f) and spallation (h) of a blister on the convex surface of the turbine blade. The frame number is counted from the start of each second.

The just-discernible small spot (circled in red) in image (b) is clearly much smaller than the buckling radius of 2.38 mm that is calculated using the conventional buckling-driven approach with Eq. (41) and $\alpha = 1.22$. This nucleation radius is difficult to see in a still image; it is much clearer to see by playing a video recording. A sharpened and magnified view is also provided in the insert in image (b). According to the PECs hypothesis, PECs are the source of energy that is required to nucleate the blister, which due to its size cannot be explained by the conventional buckling-driven approach. The required nucleation energy predicted by the mechanical model is given by Eq. (64).

After nucleation (b), the blister took about 1 s to grow steadily and its radius reached about 1.1 mm in (c), which is still smaller than the buckling radius of 2.38 mm. According to the PECs hypothesis, the blister growth during this stage is being driven by PECs.

One frame after image (c) (i.e. 0.033 s later), the blister suddenly grew into the non-circular shape in (d). This is considered to be unstable growth, which according to the PECs hypothesis is driven by both buckling and PECs. The radius for the initiation of the unstable growth is therefore taken as 1.1 mm, as measured from (c). The corresponding radius from the mechanical model is given by Eq. (39), or by the approximate Eq. (41).

From image (c) onwards, the blister is viewed as having a circle-shaped part plus initially one branch (d–e) and then two branches (f–h). The circle-shaped part is very close to circular and it is natural to fit a circle to this part of the blister, as demonstrated in (h). Note that although the blister is strictly non-circular, it is not significantly less circular than some of the alumina scale blisters shown in Ref. [26], for which diameter measurements are still taken. By using this approach, the radius of the right half-circle in (d) is measured as 2.5 mm, and in (e) as 2.8 mm. Images (e) to (g) show further unstable growth of the blister, which according to the PECs hypothesis was still being driven by both PECs and buckling. One frame after (e) (i.e. 0.033 s later), the blister branched (f); however, the right half of the blister retained its circular shape with a radius of about 2.8 mm. Following that, up until image (h), the blister continued to grow rapidly and unstably in both branching directions and also radially in the right half-circle area. The right half-circle radius in (g) is measured as 3.1 mm, and ridge cracks are also visible. In (h), the blister and ridge cracks have extended further still, and the radius of the right half-circle is measured as 3.3 mm. Image (h) is regarded as the spallation radius since it represents the end of this period of rapid unstable growth. Note that the blister in (h) has not yet spalled off to expose the BC even though it has reached its spallation radius. This is because the blister energy cannot have been great enough to crack through the TGO and TC. 12 s after image (h), the branches extended very rapidly and detached from the substrate. This final stage of blister growth and spallation is considered later.

The measured radii are compared with the corresponding radius predictions from the mechanical model in **Table 3**. Note that R_b at spallation does not depend on α , and so the predicted values are given only once in **Table 3** and are not repeated for each value of α . As before, ‘E’, ‘T’ and ‘2D’ denote the use of classical plate partition theory, first-order shear-deformable plate partition theory, and 2D elasticity partition theory respectively in the mechanical model. In addition, G_c and Ω from the mechanical model with the E, T and 2D theories are summarized in **Table 4**. These are the Ω values used in **Table 3** to predict the initiation of unstable growth with Eqs. (39) and (41), and to predict the spallation radius with Eqs. (50) and (51). Based on $\xi = 0.483$ for this experiment, the Ω values are all significantly

larger than $2\alpha^2\xi$ and $(1+\xi)$, as required by Eqs. (39) and Eq. (50) respectively; hence, Eqs. (41) and (51) give good approximations. Note that the predicted spallation radius is slightly smaller than the measured one. As discussed in Section 2.4.1, this may be because of the appearance of ridge cracks which consume a small amount of blister energy.

Table 3 Circular blister radius comparison for the initiation of unstable growth and spallation.

α	R_B at initiation of unstable growth (mm)					R_B at spallation (mm)				
	Eq. (39)			Eq. (41)		Eq. (50)			Eq. (51)	
	E	T	2D	All	Test data	E	T	2D	All	Test data
0.652	1.28	1.28	1.28	1.27	1.1±0.1					
0.936	1.84	1.85	1.84	1.83	image	3.45	3.49	3.46	3.43	image
1.22	2.40	2.43	2.41	2.38	(c)					(h)

Table 4 G_c , λ , and Ω from the mechanical model based on the classical plate, first-order shear-deformable plate and 2D elasticity partition theories.

	G_c (J m ⁻²)	Ω
	Eqs. (31), (56), (59)	Eqs. (40), (57), (60)
E	8.400	23.966
T	17.951	11.215
2D	10.683	18.845

The lowest value of unstable growth radius predicted by the PEC-based mechanical model is 1.27 mm by taking $\alpha = 0.652$. In contrast, the lowest value of unstable growth radius predicted by the conventional buckling-driven approach is slightly larger than 2.38 mm, which is given by taking $\alpha = 1.220$. The measured radius at the initiation of unstable growth is 1.1 mm, which is close to the lowest value predicted by the PEC-based mechanical model.

The measured spallation radius is 3.3 mm, which is close to the analytical prediction of 3.4 mm (independent of α), despite the appearance of ridge cracks in (h). These experimental observations, together with their good agreement with the PEC-based mechanical model, strongly support the hypothesis that TBC spallation is driven by both PECs and buckling in what represents a new spallation mechanism.

In the experiment, no straight blister nucleation or growth was observed; however, some straight-edged spallation did eventually occur, growing out of the top of the original blister, as shown in **Figure 6** in image (i) of the sequence. The average half-width of the straight-edged spallation indicated on **Figure 6** is 3.2 mm. This frame is from just after the coating flaked off, and it is therefore considered to be the straight blister spallation half-width for this TBC. The corresponding half-width values from the mechanical model are compared in **Table 5**. Note the mechanical model predicts that the spallation half-width of a straight blister is identical to the spallation radius of a circular blister. The measured half-width of 3.2 mm is slightly smaller than the predicted value of 3.43 mm. The difference is likely due to ridge cracking, which the current mechanical model does not consider; however, as discussed in Section 2.4.1, the predicted spallation half-width being slightly smaller than the measured one is consistent with ridge cracking consuming a small amount of blister energy.

	Eq. (50)			Eq. (51)	Test data
	E	T	2D	All	
Half-width (mm)	3.45	3.49	3.46	3.43	3.2±0.1

5 Conclusions

TBC spallation failure reduces the reliability and durability of turbine blades on gas turbine engines. TBC blisters can develop with circular and straight delamination edges as well as with other more-complex shapes. To investigate the mechanics of TBC spallation, a whole new turbine blade with an EBPVD TBC was isothermally heated and cooled to room temperature in cycles. After a certain number of cycles, the TBC eventually spalled off shortly after reaching room temperature under constant biaxial compressive residual stress. The blister layer comprised the TC and TGO. The observed spallation sequence began with blister nucleation,

which at first grew stably, and then grew unstably with branching, before the TBC finally flaked off. Blister nucleation occurred at a much smaller size than the critical buckling size, which proves that the spallation process cannot be explained by the conventional buckling-driven approach.

The authors' PECs hypothesis [12,13] says that PECs provide the additional source of energy that is required for a blister to nucleate and grow. The conventional buckling-driven approach has no such requirement. A mechanical model based on this hypothesis of PECs was developed to explain and predict the experimental observations. The mechanical model accounts for arbitrary through-thickness variations of material properties and degree of cooling, which attempts to accurately capture the condition of a real turbine blade in cooling.

The blister sizes at the initiation of unstable growth and at spallation, as measured and as predicted by the mechanical model, are in close agreement. Moreover, the mechanical model provides two conditions for the spallation of TBCs: (1) PECs must be able to supply sufficient energy to take the blister energy to the blister energy capacity $(U_a)_{MUE}$ in Eq. (49). After this point, the blister has stored enough energy in itself to continue propagating with no further energy requirement. (2) The ratio between the in-plane strain energy per unit width and the interface adhesion toughness, Ω , must be greater than $(1 + \xi)$, where $\xi = (AD - B^2)/(2AD)$. These two conditions provide valuable guidance for TBC design and optimisation to avoid spallation failure.

The spallation behavior observations described above, together with the accuracy of the developed mechanical model, strongly suggest that a new mechanism of spallation has been discovered. It is now necessary to conduct further research to discover the source of PECs and their development under real operational conditions in order to improve the lifetime, lifetime variation, and operating temperature of turbine blades and other engine components with TBCs. When linked together with the source and development of PECs, this work is expected to provide the framework and understanding for significant improvements in future turbine blade design.

Data availability

The authors confirm that the data supporting the findings of this study are available within the article.
