INVESTIGATION OF THE APPLICATION OF AN ENZYME–BASED
BIODEGRADABILITY TEST METHOD TO A MUNICIPAL SOLID WASTE
BIODRYING PROCESS

Abstract

This paper presents a study to evaluate the recently developed enzymatic hydrolysis test (EHT) through its repeated application to a waste treatment process. A single waste treatment facility, involving a biodrying process, has been monitored using three different methods to assess the biodegradable content of the organic waste fractions. These test methods were the anaerobic BMc, aerobic DR4 and the EHT, which is a method based on the enzymatic hydrolysis of the cellulosic content of waste materials. The input municipal solid waste (MSW) and the output solid recovered fuel (SRF) and organic fines streams were sampled over a period of nine months from a single mechanical biological treatment (MBT) facility. The EHT was applied to each stream following grinding to <10 mm and <2 mm, in order to investigate the effect of particle size on the release of dissolved organic carbon (DOC) from enzyme hydrolysis. The output organic fines were found to more biodegradable than the MSW input and SRF output samples in each of the test methods, significantly (p<0.05) for the EHT and DR4 methods, on the basis of DOC released and oxygen consumed respectively. The variation between sample replicates for the EHT was higher where sample sizes of <2 mm were analysed compared to sizes of <10 mm, and the DOC release at each phase of the EHT was observed to be higher when using particle sizes of <2 mm. Despite this, additional sample grinding from the <10 mm to a smaller particle size of <2 mm is not sufficiently beneficial to the analysis of organic waste fractions in the EHT method. Finally, it was concluded that as similar trends were observed for each test method, this trial confirms that EHT has the potential to be deployed as a practical operational biodegradability monitoring tool.
1. Introduction

In accordance with the EU Landfill Directive, the amount of biodegradable municipal waste (BMW) disposed of in landfill needs to be dramatically reduced (Council of the European Union, 1999). The BMW proportion of municipal solid waste (MSW) can be reduced via treatment of the waste material in processes such as mechanical biological treatment (MBT) which involve the separation of solid recovered fuel (SRF) and biological treatments such as composting or anaerobic digestion (Archer et al., 2005). Methods of assessing the biodegradable content of input and output materials of the treatment processes can provide important information on process performance and the diversion of BMW from landfill (Wagland et al., 2009). There is a general acceptance that all test methods have their advantages and limitations but the suitability of the available test methods for routine operational use remains the subject of academic debate (Sánchez, 2009; Wagland and Tyrrel, 2010), suggesting a requirement for further research and development into alternative methods. One such method is the enzymatic hydrolysis test (EHT) (Wagland et al., 2009). This procedure uses a mixture of hemicellulase and cellulase enzymes, under optimum conditions, to hydrolyze the biodegradable substrate (Wagland et al., 2007). These enzymes are used as BMW consists of 30-50% lignocellulosic material (Godley et al., 2007a; Rodriguez et al., 2005; Wagland et al., 2008), and hemicellulose/cellulose can contribute to up to 90% of the
total biogas (CO₂/CH₄) produced under anaerobic conditions, such as landfill (Barlaz et al., 1989).

In the recent study by Wagland et al. (2008) the BM100, DR4 and EHT methods were applied to a wide range of untreated and treated organic waste materials including MSW, garden waste, food waste and sewage sludge. The BM100 is an anaerobic test method which measures the biogas (CO₂ and CH₄) release over a period of 100 days; and the DR4 is a dynamic 4 day aerobic test which measures the oxygen consumption of biodegradable material under aerobic conditions (Wagland et al., 2009). The correlations of the short-term EHT and DR4 methods with the long-term BM100 test method were compared. The EHT generated a stronger correlation with the BM100 than that of the DR4 (r = 0.77 and 0.58 respectively) indicating that the method has some potential and should be subject to further testing. The use of the EHT test remains debatable, however, due to concerns that the test will not register the biodegradable content of wastes with a relatively low composition of polysaccharides (Wagland et al., 2008). Biological methods are commonly recognized as suitable approaches, capable of high correlations with long-term anaerobic methods for specific waste streams and treatment processes (Cossu and Raga, 2008; Ponsá et al., 2008; Sánchez, 2009).

The BM100 test for monitoring BMW diversion from landfill has been superseded and is now referred to as the biodegradability under methanogenic conditions (BMc) (Environment Agency, 2005; Turrell et al., 2009). Therefore, currently in the UK the aerobic DR4 and BMc test methods are used to monitor BMW diversion from landfill (Environment Agency, 2005; Godley et al., 2007b; Turrell et al., 2009). In this study the EHT, DR4 and BMc methods were applied to a series of samples taken over a nine month
period from a single MBT facility which employs a 2 week biodrying process. The principal aim was to evaluate the performance of EHT as a biodegradability test when applied in the context of the routine monitoring of a waste treatment facility. In addition to monitoring the changes in biodegradability, the waste samples were assessed using different particle sizes for the EHT. The surface area of the waste material is likely to affect the rate and extent to which the enzymes hydrolyze the substrate. It was hypothesized that grinding to smaller sample sizes would result in less variability between sample replicates, and so a smaller <2 mm particle size was used in addition to the standard <10 mm used in the DR4 and BMc test methods. Also the increased surface area: particle volume ratio may result in a significantly higher dissolved organic carbon (DOC) release, which has been observed previously (Dasari and Eric Berson, 2007). Therefore this study investigated the effects of particle size on variation and DOC yield for the EHT in addition to the monitoring of an MBT process using UK-established biodegradability test methods, to indicate the suitability of the EHT method for assessing the biodegradable content of MSW-derived material.

2. Methods

2.1. Samples

The samples were collected from a single MBT facility located in the south of England. This facility receives general mixed MSW collected from the local area. The waste material is shredded and placed in a large composting hall for 2 weeks where it is dried using the heat generated by microbiological activity (biodrying) before passing through a complex separation process (Figure 1).
The composting halls consist of a perforated floor and ductwork system, which allows air to be drawn downwards through the waste. This aerates the waste material, and also provides the fully enclosed facility with a negative air pressure, which minimises the release of odours. The biological processes which occur in composting result in increased temperatures, between 50 and 60°C, which evaporate the water content of the material resulting in a mass reduction of approximately 25% (Ecodeco, 2001a). The biodrying process provides a dried waste material, which allows for the separation of low density material (e.g. shredded paper, fabric etc) from the heavier glass and inert fractions. From the extraction hopper (Ecodeco, 2001b) fractions of metals (ferrous and non-ferrous), inert materials (glass, stones, brick etc), fines, and SRF are separated. The SRF fraction consists of combustible material, such as paper, card, wood and fabric. The SRF can therefore be used in incinerators as a fuel. The fines fraction is removed from the waste material (typically <20 mm after primary shredding) by passing over a <6 mm screen.

The samples used in this study were the MSW input, solid recovered fuel (SRF) and fines output materials. The SRF and organic fines are output materials which are expected to represent the organic fractions of the waste material post-biodrying. The fines were expected to be organic materials derived from food waste. The samples were collected at least fortnightly, in 10 x 2 kg batches, which were then thoroughly mixed to make up the composite sample of the waste material, and ‘coned and quartered’ to obtain a representative 2-3 kg analytical sample from the total batch (Environment Agency, 2005; Turrell et al., 2009).
The samples were sorted to remove glass, metals, plastics and inert materials with the biodegradable material being retained and tested (Environment Agency, 2005). The samples were dried at 70°C to 80-90% dry weight and shredded using an adjustable grinder to <10 mm and <2 mm. The standard particle size of <10 mm (Environment Agency, 2005) was used for the EHT, DR4 and BMc analysis, whilst the smaller <2 mm particle size was only used in EHT analysis as part of an exploration to assess the effects of particle size on the DOC yield and variation between sample types. The samples were analysed immediately, or otherwise stored in sealed containers in a cold room (<4°C) until required. Each of the samples was subsampled and tested in triplicate, and the results expressed are the mean values obtained.

2.2. Aerobic DR4

Biodegradability under aerobic conditions was determined using the DR4 test method (Environment Agency, 2005; Godley et al., 2007b; Godley et al., 2005). The test material (100 g dry matter (DM)) was mixed with a seed material (100 g DM), which was a mature green waste compost. Water and nutrients (nitrogen, as 2 M ammonium chloride, and phosphorus, as 1 M potassium phosphate) were added to adjust to 50% w/w moisture content, based on the measured %DM of the sample. The test mixture was placed in a reactor vessel at 35°C for 4 days, with constant aeration (500 ml/min (Environment Agency, 2005)) through the test material. The O₂ consumed during the 4 days was estimated from the amount of CO₂ released, which was measured by using 1 M NaOH solutions to ‘trap’ CO₂ and then titrated against 1 M HCl (Turrell et al., 2009). The volatile solids (VS) content, referred here as loss on ignition (LOI) (European
Committee for Standardisation, 2005) for each sample was determined; and the results expressed in terms of the LOI content of the test material (mg O/kg LOI) (Environment Agency, 2005).

2.3. Anaerobic BMc

The BM100/BMc test method (Environment Agency, 2005; Turrell et al., 2009) is based on a sewage sludge digestion test (Godley et al., 2007b; Godley et al., 2003). The test material (20 g LOI) was placed in a 350 ml glass container with 50 ml/l microbial seed (digested sludge) and a nutrient mixture. The mixture was sealed and incubated at 35°C under anaerobic conditions and the release of CO₂ and CH₄ (biogas) was measured volumetrically until no further biogas was released (up to 100 days). The results are expressed as the volume (litres) of biogas generated per kg of LOI of the test material (l/kg LOI) (Environment Agency, 2005).

2.4. Enzyme hydrolysis test

The EHT was applied as described in previous studies (Wagland et al., 2008; Wagland et al., 2007). For each sample 25 mg of crude cellulase powder (Sigma, C9422) and 75 mg of hemicellulase powder (Sigma) were dissolved in 20 ml of distilled water. According to the manufacturer’s specification, each 20 ml of enzyme mixture possessed approximately 175 units of cellulase and 112.5 units of hemicellulase activity. According to the manufacturer’s specification, the crude cellulase powder was expected to exhibit some hemicellulase and protease activity, and the hemicellulase enzymes some
cellulase activity. To sterilise the enzyme solution it was then filtered through a 0.22 μm Millipore membrane.

The test method consists of three phases as follows:

i. The test material (5 g LOI) was placed in a 250 ml Erlenmeyer flask. Phosphate pH buffer (100 ml 0.37 M) was then added to the flask. A 5 ml sample was removed and filtered (0.45µm membrane filter) to remove any solids, and the filtered liquid was then analysed for chemical oxygen demand (COD) (Spectroquant COD test tubes).

ii. The sample mixture was then autoclaved at 121°C for 15 min to sterilise the mixture and a further 5 ml sample was removed and filtered for COD analysis.

iii. The prepared enzyme solution (20 ml) was then added to each of the flasks and the flask sealed with a neoprene bung. The flasks were placed in a shaking incubator at 150 rpm for 20 h at 50°C. A final 5 ml sample was then removed for COD analysis.

The amount of moisture in the waste sample and the removal of both the liquid and solids at each stage of sampling, along with the addition of liquid in phase 3, were accounted for in the concentrations of carbon calculated. Soluble COD analysis results were converted to DOC (mg C/l) by assuming a COD/C ratio of 2.67 based on the relative molecular mass of cellulose monomeric units.

To assess the effect of particle size on DOC yield and variation between replicates the following was considered:

- Post-autoclave DOC [P2];
• Total DOC [P3];
• Enzyme-only DOC [P3-P2]

To assess the biodegradable content of the samples only the total DOC [P3] was considered.

3. Results
3.1. Biodegradability of the Sample Fractions

The average biodegradability values obtained for the individual waste fractions for each of the biodegradability test methods are shown in Table 1 and Figure 2. The number of samples (n) for the MSW input, SRF and fines was 8, 11 and 6 respectively.

The values obtained from the BMc, DR4 and EHT test methods indicated that the fines fraction contained the most biodegradable material. The DR4 and EHT test methods suggest that the fines material was significantly more biodegradable than the MSW input and SRF output (P<0.05, two-tailed t-test). For the BMc method the difference between the fines material and the MSW were significant (P<0.05, two-tailed
t-test) but not for the difference in biodegradability between the fines and the SRF. The MSW input and SRF samples were in each case very similar in biodegradable content. For each of the methods, the difference in biodegradability between MSW and SRF was not statistically significant (P>0.1, two-tailed t-test).

3.2. Effect of Particle Size in the EHT

The particle size of the waste samples had an effect on the DOC released at each phase of the EHT. This is shown in Figure 2. As expected, the DOC released over the course of the EHT method increased after each phase of the process. In terms of the total DOC (final phase 3 value) the fines material was the most biodegradable (P<0.05, two-tailed t-test), whereas the MSW input and SRF output samples were not significantly different (P>0.1, two-tailed t-test).

The coefficient of variation ($C_v$) for each set of results was calculated from the following equation:

\[ C_v = \frac{\sigma}{\mu} \]  

Equation 1

Where $C_v$ is the coefficient of variation, $\sigma$ is the standard deviation and $\mu$ is the mean. $C_v$ is useful since this is a normalised statistic allowing comparison between the three methods used. The $C_v$ for each sample at each phase of the EHT is shown in Table 2.
Table 2. Coefficient of variation at each phase of the EHT for MSW, SRF and organic fines samples.

</table>

The $C_v$ was consistently higher for the <2 mm samples of MSW and organic fines, whereas the $C_v$ was lower for samples <2 mm for the SRF materials.

4. Discussion

4.1. Biodegradability of the Sample Fractions

The aim of this study was to investigate the suitability of the EHT to monitor a waste treatment process over a prolonged period of time by comparison with standardised biodegradability tests. Each of the three methods produced comparable results which indicated that the MSW input and SRF output samples were similar in terms of their biodegradability whereas the fines fraction was consistently more biodegradable. The extent of variation between samples was comparable in each of the tests (Table 3) indicating that the tests produce consistent measures of biodegradability over an extended sampling period and suggesting that the waste fractions tested were also consistent over the monitoring period.

The biodegradability of the MSW input and the SRF output materials was found to be very similar. It was originally expected that the MSW input material would be more biodegradable than the SRF material. However, it is apparent from these results that the biodegradable content of the MSW input is not reduced significantly (P>0.1) due to the relatively short composting period employed in the biodrying process, which is only designed to dry the waste material, and not to bio-stabilise it.

In spite of the biodrying process, the fines output sample was found to be more biodegradable than the MSW input since this material has had the more slowly biodegradable materials removed (such as cardboard, wood and fabrics), with the readily biodegradable materials, such as food waste (vegetable peelings, meat residues etc) effectively becoming more concentrated. The DOC released during the EHT, along with the DR4 values, suggest that the fines material is significantly (P<0.05) more biodegradable than the MSW input and SRF output materials. The DR4 values for the fines material were 68% and 82% higher than the MSW input and SRF samples respectively, whilst for the total DOC (P3) of the EHT, the DOC output from the fines
material was 109% and 106% higher than that generated from the MSW input and SRF samples respectively. However the difference in biodegradability between the fines fraction and the other fractions was lower for the BMc compared to the DR4 and EHT tests. The BMc value for the fines material was 31% higher than the SRF output (P<0.05), and 24% higher than the MSW input (P<0.1). This difference in relative biodegradability between fractions is likely to be because the BM100/BMc test method measures the full extent of biodegradability (Godley et al., 2007a; Godley et al., 2007b; Wagland et al., 2008), and so will completely hydrolyse a higher proportion of the more slowly biodegradable carbon (such as cardboard and wood) in the MSW input and SRF samples than the EHT and DR4 methods.

4.2. Effect of Particle Size in the EHT

Grinding of the sample to a smaller size was expected to have an effect on the DOC yield and the variation observed between sample replicates. Grinding to <2 mm was expected to yield higher DOC release due to the increase in surface area: volume ratio of each particle.

As shown in Figure 2 the DOC release at each phase proved to be largely unaffected by particle size with the exception of the fines fraction (P2). Reductions in particle size have been observed to yield higher rates of enzyme hydrolysis of cellulose in a previous study by Dasari and Berson (2007). In their study particle sizes of 33 µm to 850 µm were investigated, and up to 55% more glucose was produced from cellulase hydrolysis of the smallest particles than for the largest particle sizes (Dasari and Eric Berson, 2007). Whilst the particle sizes used in this study were considerably larger than
those used by Dasari and Berson (2007), the same principle would be expected to apply. This suggests that the enzymes used in the EHT test were able to access biodegradable substrate even in the centre of 10 mm particles.

The use of a smaller sample particle size was also expected to generate a more uniform sample, and therefore provide lower variation between sample replicates. A greater surface area: particle volume ratio allows higher enzyme coverage, and it was postulated that for larger particle sizes the enzymes would be able to access the middle of the substrate to varying degrees in the relatively short incubation time, and that it was more likely that all available substrate will be hydrolysed in the given timescale (20 h) for the smaller particles. This however did not prove to be the case.

The use of samples of a smaller particle size resulted in a higher DOC release at each phase, however in each case (except fines P2) the differences between DOC release between <10 mm and <2 mm were not statistically significant (p ≥ 0.1). The difference between DOC release at P2 for the Fines sample at <10 mm and <2 mm was significant (p<0.05), however the difference at P3 was not (p>0.1). This would suggest that the EHT would not benefit from further sample grinding from <10 mm (currently the DR4 and BMc requirement) to <2 mm. As shown in Table 2, since the coefficient of variation (C_v) for the samples of smallest particle size (<2 mm) is higher than that of the larger particle sizes (<10 mm), there is no benefit in terms of improved consistency. This means that the sample preparation currently used for the DR4 and BMc methods (grinding to <10 mm) is suitable for the EHT.

Whilst not statistically significant, for the MSW and SRF materials a greater amount of DOC was released from the sample during autoclaving for the <2 mm samples
than for <10 mm. This supports the findings in previous studies, where it was observed that the hydrolysis of hemicellulose and, to an extent, cellulose and lignin is catalysed by mild acid under high temperatures (Jacobsen and Wyman, 2000; Nguyen et al., 1998; Torget et al., 1990). The effects of a high energy pre-treatment process (such as autoclave) of waste material was also reported to cause the slowly biodegradable materials to be more accessible and easier to decompose (Tojo et al., 2007). However as the difference resulting from additional grinding was not statistically significant, this extra sample preparation is not necessary for the EHT method.

As shown by Wagland et al (2008) the EHT and DR4 correlate, to varying degrees, with the BM100/BMc. However since each test method has limitations and measures different parameters, a correlation of $r = 1.0$ is very unlikely. The BMc test is sensitive to highly biodegradable substrates, in which acidic conditions can inhibit methanogenesis (Environment Agency, 2005), thus affecting the final results. The DR4 test method is responsive to readily biodegradable material, but due to its short duration can potentially underestimate the presence of slowly biodegradable materials. The DR4 therefore only measures the initial rate of biodegradation (Godley et al., 2007a; Godley et al., 2007b). The EHT doesn’t have the biological disadvantages associated with the DR4 and BMc methods, however may not measure the full extent of biodegradation in the given timescale because of the inherent limitations associated with providing a suitably diverse range of enzymes and conditions to ensure their sustained activity. As discussed by Wagland et al (2008), the DOC released at P2 may contain varying quantities of DOC comprising biodegradable and non-biodegradable fractions, likewise P3 may contain DOC of both biodegradable and non-biodegradable natures, and therefore further
investigation is required to sufficiently determine only the biodegradable DOC. All
currently available test methods have their limitations. However, this extended
comparison with accepted methods suggests that the EHT is able to produce comparable
and consistent results and therefore shows promise as an operational monitoring tool.
Further development of the test is needed, for instance the use of a more complex enzyme
mixture to ensure that the biodegradability of a wide range of materials including fats and
proteins is measured.

4. Conclusions

- Each of the biodegradability methods used in this study generated consistent values of
  relative biodegradability for the three sample types tested.

- The fines material was found to be significantly more biodegradable than the MSW
  input and SRF output materials in all three test methods. It was found that the BMc
  test indicated a smaller difference in MSW and SRF biodegradability relative to the
  fines samples. This was attributed to the likelihood that the BMc was more likely to
  have hydrolysed a higher proportion of the more slowly biodegradable compounds
  present in the MSW input and SRF samples

- The use of particles of <2 mm in the EHT test did not release appreciably higher
  amounts of DOC from the waste samples tested. The variation between sample
  replicates for the EHT was significantly higher where sample sizes of <2 mm were
  analysed compared to sizes of <10 mm. Therefore it is not necessary to grind the
  samples from the <10 mm used in the BMc and DR4 methods to <2 mm.
