Abstract: Solar aided coal-fired power system has been proven to be a promising way to utilise solar energy in large scale. In this paper, the performances of the solar tower aided coal-fired power (STACP) system at 100% load, 75% load, and 50% load for different days are investigated and the maximum solar power that the boiler can absorb under different plant loads are explored. Then, the effects of solar multiple (SM) and the thermal energy storage (TES) hour on the daily performance of STACP system are investigated. Results show that the maximum solar power that a 600 MW\textsubscript{e} boiler can absorb at 100% load, 75% load and 50% load are 76.4 MW\textsubscript{th}, 54.2 MW\textsubscript{th} and 23.0 MW\textsubscript{th}, respectively. Due to the augmented energy from the solar field, the maximum standard coal consumption rate is reduced by 13.53 g/kWh, 12.81 g/kWh and 8.22 g/kWh at 100% load, 75% load and 50% load, respectively. With an increase of solar power input, the boiler efficiency, overall system efficiency and solar thermal-to-electricity efficiency shown a downward trend. In addition,
the daily coal consumption of summer solstice is the lowest while the winter solstice is the highest for a particular SM and TES hour.

1. Introduction

In developing countries, coal is still the main energy source to generate electricity at present
With increasing concerns on serious environmental problems caused by coal-fired power plants and fossil resource shortages, it is important to reshape the energy structure and exploit renewable energy to replace the coal. Compared with wind power and photovoltaic, concentrated solar power (CSP) with thermal energy storage can generate stable un-interrupted electricity for different solar radiation condition, which seems to be a promising technology to replace coal as the main power generation technology. However, conventional standalone CSP plants face a lot of difficulties at present, such as the huge investment, lower efficiency compared to fossil fired plants and large scale of thermal energy storage (TES) system requirements, which hinder the large-scale utilisation of solar energy [4, 5]. Integrating solar thermal energy into coal-fired power plant, also known as solar aided coal-fired power (SACP) system, has the potential to reduce the coal consumption in coal-fired power plant and overcome the above mentioned drawbacks of CSP Plants as well [6].

The earliest work of SACP system was conducted by Zoschak and Wu in 1975 [7]. They investigated seven different ways of integrating solar thermal into an 800 MW e coal-fired power plant. Results show that combing solar energy with coal-fired power system is a promising way to use solar energy. The solar-coal hybrid systems are gaining interest in recent years. System integration is the first important problem need to be solved in this area. Hu et al. proposed a SACP system that used solar energy to preheat the feed-water and the results indicated that SACP system is an economical way for solar energy utilisation [8]. Yang et al. considered a 200 MW e coal-fired unit as an example and investigated four different integration schemes, and the results show that the solar thermal to power efficiency can be over 36% for the solar heat at 260 °C [9]. Then, the thermal performance [6, 10-13], economic performance [14, 15] and off-design performance [5, 6, 16] were...
studied on the SACP systems. Recently, researchers paid more attention to the optimisation and evaluation method of the SACP system. On the optimisation aspect, Zhao et al. presented an economic benefits of the solar multiple for SACP system with different unit scales [17]. Zhong et al. proposed an operation optimisation strategy for SACP system and applied a mixed-integer nonlinear programming approach to optimise the oil-water heat exchanger area with an optimised operation parameters based on the annual direct normal irradiance (DNI) distribution [18]. Sun et al. optimised the tracking strategy for the parabolic trough collector and results showed there was a boost about 15–17% in collector efficiency [19]. In terms of the evaluation method, Zhai et al. used life cycle assessment method to evaluate the SACP system [20]. Peng et al. applied the energy-utilisation diagram methodology to the SACP system [21]. Hou et al. proposed a new evaluation method of solar contribution in a SACP system based on exergy analysis [22]. Wang et al. evaluated different modes of solar aided coal-fired power generation system through theoretical calculations [23]. These studies indicated that SACP system is a promising way for the large scale utilisation of solar energy with high efficiency and can reduce the fossil fuel load in the coal-fired power system.

Zoschak and Wu’s study has showed that integrating solar energy with the evaporation and superheating can achieve more profit than using solar energy to preheat feed-water [7], because the temperature of superheat steam is normally over 500 °C, which is much higher than the temperature of feed-water (lower than 300 °C). Therefore, higher operation temperature of solar field is necessary and solar tower technology is used to assist the coal-fired power system, also known as solar tower aided coal-fired power (STACP) system. STACP system could achieve higher power efficiency than that of traditional SACP system, because solar energy with higher temperature is used in this system. Zhang et al. proposed two schemes of introducing the solar tower with 660 MWe coal-fired power
plant, and investigated the performance at the design point and the annual performance of the integrated solar tower with a single tank thermocline storage system [5, 24]. Zhu et al. studied the solar tower aided coal-fired power system by performing exergy analysis and techno-economic analysis [25, 26]. Then, the annual performance was investigated and the annual average results show that the reduction of coal consumption rate and the CO$_2$ emission rate were about 27.3 g/kWh and 10.1% respectively compared with coal-fired power system [1].

Based on authors’ detailed literature review, it can be highlighted that the off-design performance study of STACP system is inadequate and the effects of solar multiple (SM) and TES hour are not yet studied. As the solar energy introduced increases, the amount of water/steam exacted from the boiler also increases, thus the amount of heat absorbed and the inlet and outlet temperature of each heater will change as well. When the solar energy increases to a certain extent, it is difficult to maintain the temperature of superheat steam and reheat steam by adjusting the coal consumption rate at the same time. Therefore, the maximum solar energy that the boiler can absorb has to be determined. In our previous study, the STACP system which uses solar tower energy to replace the thermal load of water wall and super-heaters in the boiler has demonstrated better thermal performances than other integration schemes [27]. Therefore, the novelty of this study lies in that: (1) Calculating the maximum solar power that the boiler can absorb ($Q_{boiler,max}$) for the above mentioned STACP system at 100% load, 75% load, and 50% load. (2) Exploring the thermal performance of the STACP system with different solar energy shares for the selected loads. (3) The impacts of SM and TES hour on the daily performance of STACP.

2. System description

2.1 Solar tower aided coal-fired power system
Fig. 1 shows a schematic diagram of the STACP system, which is composed of the “solar part” and the “coal-fired part”. The “solar part” contains heliostats, a solar tower, a columnar receiver, the TES system and a heat exchanger. The solar energy is reflected onto a receiver by the heliostats. After absorbing the solar energy in the receiver, the hot molten salt flows into the hot tank. According to the operation strategy of STACP system, the flow rate of the molten salt out of the hot tank can be adjusted. After releasing thermal energy to the steam/water in the molten salt heat exchanger (MSHE), molten salt flows into and stores in the cold tank. Then the cold molten salt is pumped to the receiver for further solar energy collection. The molten salt used is a mixture of 60% NaNO$_3$ and 40% KNO$_3$ and the properties of the molten salt are as follows [28]:

\[
\rho = 2263.72 - 0.636T \quad (1)
\]
\[
c_p = 1396.02 + 0.172T \quad (2)
\]
\[
\lambda = 0.391 + 0.00019T \quad (3)
\]

Where $\rho$ is the density of molten salt; $c_p$ is the specific heat of molten salt at constant pressure; $\lambda$ is the thermal conductivity of molten salt; $T$ is the temperature of molten salt.

In this study, we consider a supercritical coal-fired power plant which is based on single-reheat and condensing steam turbines arrangement with rated capacity of 600 MW$_e$ at the design point. The thermal parameters of the main steam and reheat steam are 566/24.2 and 566/3.6 (℃/MPa), respectively.

In the “coal-fired part”, the unsaturated feed-water from the condenser enters into the boiler after going through condensate pump, four low pressure heaters (H5, H6, H7, and H8), a deaerator (H4), feed-water pump and three high pressure heaters (H1, H2, and H3). Feed-water from the high pressure heaters first goes to the economizer (ECO). The water out from the ECO is divided into
two parts. One part flows into the heat exchange to absorb solar energy in the “solar part”. The other part flows into the water wall from the bottom of the boiler, where the water partially turns into steam due to the radiative heat absorption from the furnace flame. Then the steam/water mixture enters to the steam separator (SEP), where the steam is separated and passes through first platen super-heater (FPS), second platen super-heater (SPS) and final super-heater (FS). Then, the superheat steam mixes with the steam from the “solar part” and enters to the high pressure turbine (HP) to produce power. Later, the steam out from HP returns back to the boiler to be reheated in the low-temperature re-heater (LR) and high temperature re-heater (HR) to improve the work capacity and efficiency by increasing the average heat addition temperature. Then, the reheat steam is transported to the intermediate pressure turbine (IP) and the low pressure turbine (LP) to produce further electric power, finally exhaust steam is condensed in the condenser.

Fig.1 The diagram of solar aided coal-fired power system (red line: steam; blue line: water; green line: extracted water/steam)

2.2 Operational Strategies

The operation strategies of the STACP system with thermal storage system are mainly
dependent on the relationship between solar energy collected by the receiver \( (Q_{rec}) \), solar energy stored in the hot tank \( (Q_{ht}) \) and maximum solar energy that can be absorbed by the boiler \( (Q_{boiler,max}) \), and the following six conditions are defined as:

(1) When \( Q_{rec} \geq Q_{boiler,max} \), the solar energy absorbed by the boiler is \( Q_{boiler,max} \) and the extra solar energy is stored in the hot tank.

(2) When \( Q_{rec} < Q_{boiler,max} \) and \( Q_{ht} \geq Q_{boiler,max} - Q_{rec} \), the solar energy absorbed by the boiler is \( Q_{boiler,max} \).

(3) When \( Q_{rec} < Q_{boiler,max} \) and \( Q_{ht} < Q_{boiler,max} - Q_{rec} \), the solar energy absorbed by the boiler is \( Q_{rec} + Q_{ht} \).

(4) When \( Q_{rec} = 0 \) and \( Q_{ht} \geq Q_{boiler,max} \), the solar energy absorbed by the boiler is \( Q_{boiler,max} \).

(5) When \( Q_{rec} = 0 \) and \( Q_{ht} < Q_{boiler,max} \), the solar energy absorbed by the boiler is \( Q_{ht} \).

(6) When \( Q_{rec} = 0 \) and \( Q_{ht} = 0 \), the solar energy absorbed by the boiler is 0. The STACP system operates in the standalone coal-fired power generation mode.

3. Modeling Methodology

3.1 Heliostat field

Heliostat field consists of plenty of heliostats, which can reflect sun rays to the receiver at the top of the solar tower. The thermal power reflected to the receiver can be calculated as:

\[
Q_{hel} = Q_s \cdot \eta_{hel}
\]  

(4)

Where, \( Q_{hel} \) is the solar power reflected by the heliostats. \( \eta_{hel} \) is the heliostat efficiency, which can be expressed by mirror reflectivity, cosine factor, atmospheric attenuation factor, shading and blocking factor and interception factor. The calculation method of heliostat efficiency and the
validation of the heliostat model can be found in literature [29, 30]. $Q_s$ is the solar power falling on the heliostats and can be calculated by:

$$Q_s = \text{Num} \cdot A_{\text{hel}} \cdot \text{DNI}/10^6$$

(5)

Where, Num is the number of heliostats; $A_{\text{hel}}$ is the area of a heliostat.

3.2 Receiver

The temperature of molten salt increases, when it passes through the receiver which is at the top of the solar tower. The energy balance for the receiver is as follows:

$$Q_{\text{rec}} = Q_{\text{hel}} - Q_{\text{rec,loss}}$$

(6)

$$Q_{\text{rec,loss}} = Q_{\text{ref}} + Q_{\text{rad}} + Q_{\text{conv}}$$

(7)

Where, $Q_{\text{rec}}$ is thermal power absorbed by the molten salt in the receiver; $Q_{\text{rec,loss}}$ is the thermal power loss in the receiver; $Q_{\text{ref}}$ is the thermal power loss reflected from the tube surface; $Q_{\text{rad}}$ is the radiation loss of receiver; $Q_{\text{conv}}$ is the convection loss of receiver. $Q_{\text{ref}}$, $Q_{\text{rad}}$ and $Q_{\text{conv}}$ can be obtained by [31].

$$Q_{\text{ref}} = (1-\alpha)Q_{\text{hel}}$$

(8)

$$Q_{\text{rad}} = \sum \varepsilon \sigma_0 A_r \left( T_{\text{wall,i}}^4 - T_{\text{amb}}^4 \right)$$

(9)

$$Q_{\text{conv}} = \sum h_{\text{mix,i}} A_r \left( T_{\text{wall,i}} - T_{\text{amb}} \right)$$

(10)

Where, $\alpha$ is concerning solar absorptance of the tube panels; $\varepsilon$ is hemispherical emittance; $\sigma_0$ is Stefan–Boltzmann constant, $5.67 \times 10^{-8}$ W/(m$^2$K$^4$); $A_r$ is lateral surface of the tube; $h_{\text{mix,i}}$ is mixed convection coefficient; $T_{\text{wall,i}}$ is the wall temperature; $T_{\text{amb}}$ is ambient air temperature. The receiver model is validated with data from Solar Two power plant [31, 32]. The theoretical efficiency of the receiver is 87.36%, which agrees well with the test data demonstrated as 86-88% [32]. Similarly, the other researchers quoted the receiver efficiency as 78-88% by Lata et al. [33] and 83-90% by
Jianfeng et al. [34]. Therefore, the calculated results of this model are reasonable, which means that our model is reliable.

3.3 Thermal energy storage system

The thermal storage system is of the typical two-tank type, which uses molten salt as the storage media. In this study, the TES system is assumed to operate at a steady state for an hour. The mass balance and energy balance for these two tanks are similar. Take the hot tank as an example.

\[ m_{ht} = m_{ini} + (m_{ms,in} - m_{ms,out})t_{int} \]

\[ Q_{E_{ht}} = Q_{E_{ini}} + Q_{E_{in}} - Q_{E_{out}} - Q_{E_{ht,loss}} \]

Where, \( m_{ht} \) is the mass of molten salt in hot tank; \( m_{ini} \) is initial mass in hot tank; \( m_{ms,in} \) and \( m_{ms,out} \) are the inlet/outlet mass flow rate of molten salt of hot tank; \( t_{int} \) is time interval; \( Q_{E_{ini}} \) is initial energy stored in hot tank; \( Q_{E_{in}} \) and \( Q_{E_{out}} \) are the energy in/out of hot tank for the \( t_{int} \); \( Q_{E_{ht,loss}} \) is energy loss at \( t_{int} \) and is neglected in this study.

3.4 Molten salt heat exchanger

The energy balance of the heat exchanger can be expressed as:

\[ Q_{solar} = 10^{-3} m_{ms}(h_{ms,out} - h_{ms,in}) \]

\[ Q_{wf} = 10^{-3} m_{wf}(h_{wf,out} - h_{wf,in}) \]

Where, \( Q_{solar} \) and \( Q_{wf} \) are both the power transferred to the water/steam; \( m_{ms} \) is the mass flow rate of molten salt; \( h_{ms,in} \) and \( h_{ms,out} \) are the specific enthalpy of molten salt in/out of heat exchanger respectively. \( m_{wf} \) is the mass flow rate of working fluid (water/steam); \( h_{wf,in} \) and \( h_{wf,out} \) are the specific enthalpy of working fluid in/out of heat exchanger respectively.

3.5 Boiler

Boiler model is established based on the principle that was proposed by the former Soviet
Union in 1973 and was modified in China in 1998 [35]. The calculation logical flow diagram for the boiler is shown in Fig. 2.

In furnace, radiative heat transfer is predominant and the convection heat transfer can be ignored [35]. According to energy conservation principle, the heat absorption from the flue gas in the furnace can be considered to be equal to the enthalpy drop from the adiabatic flame temperature to the temperature at the out of furnace. Therefore, the basic equation for furnace heat transfer calculation is as follows:

\[ Q_{fur} = 10^{-3} \phi B_j V_C (T_{ad} - T_{fur, out}) = 10^{-6} a_{xt} F_{fur} \sigma_0 (T_{hy}^4 - T_b^4) \]  \hspace{1cm} (15)

Where, \( Q_{fur} \) is the heat absorbed in the furnace; \( \phi \) is heat retention factor; \( B_j \) is calculation coal consumption rate; \( V_C \) is mean net heat capacity rate of the combustion products per unit; \( T_{ad} \) is adiabatic flame temperature; \( T_{fur, out} \) is the temperature at the out of furnace; \( a_{xt} \) is system emissivity; \( F_{fur} \) is furnace enclosure wall area; \( T_{hy} \) and \( T_b \) are average temperatures of the flame and the furnace wall respectively.

The convective heating surfaces refer to all the heating surfaces in the flue gas pass beyond furnace outlet. The calculation logic flow for each heater is shown in Fig. 3. The heat balance equations for the convective heating surface are as follows:

\[ Q_{con} = \frac{K A_h \Delta T_{LMTD}}{B_j} \]  \hspace{1cm} (16)

For gas side:

\[ Q_{con} = \phi (h_{flue,in} - h_{flue,out} + \Delta h_{air}) \]  \hspace{1cm} (17)

For working fluid side:

\[ Q_{con} = \frac{m_{wf} (h_{air,in} - h_{air,out})}{B_j} \cdot Q_{radiation} \]  \hspace{1cm} (18)

Where, \( Q_{con} \) is convective heat transferred; \( K \) is heat transfer coefficient; \( A_h \) is the area of heating
surface; $\Delta T_{LMTD}$ is the logarithmic mean temperature difference; $h_{flue,in}$ and $h_{flue,out}$ are the specific enthalpy of flue gas in/out of the heater; $\Delta \alpha$ is the air leakage ratio; $h_{air}$ is the specific enthalpy of cold air; $m_{wf}$ is the mass flow rate of steam/water; $h_{wf,in}$ and $h_{wf,out}$ are the specific enthalpy of steam in/out of the heater respectively; $Q_{radiation}$ is radiative heat transferred.

3.6 Turbine and feed-water preheating system

In this study, the energy balance matrix used to calculate turbine and feed-water preheating system can be expressed as:

$$
\begin{bmatrix}
q_1 \\
\gamma_2 & q_2 \\
\gamma_3 & \gamma_3 & q_3 \\
\gamma_4 & \gamma_4 & q_4 \\
\tau_5 & \tau_5 & \tau_5 & q_5 \\
\tau_6 & \tau_6 & \tau_6 & \gamma_6 & q_6 \\
\tau_7 & \tau_7 & \tau_7 & \gamma_7 & q_7 \\
\tau_8 & \tau_8 & \tau_8 & \gamma_8 & q_8 \\
\end{bmatrix}
= m_{fw}
\begin{bmatrix}
m_1 \\
m_2 \\
m_3 \\
m_4 \\
m_5 \\
m_6 \\
m_7 \\
m_8 \\
\end{bmatrix}
\begin{bmatrix}
\tau_1 \\
\tau_2 \\
\tau_3 \\
\tau_4 \\
\tau_5 \\
\tau_6 \\
\tau_7 \\
\tau_8 \\
\end{bmatrix}
$$  \hspace{1cm} (19)

Where, \( m_{fw} \) is mass flow rate of feed-water from deareator; \( m_i \) is mass flow rate of extraction steam in the \( i_{th} \) stage; \( \tau_i \) is the specific enthalpy change of feed-water in the \( i_{th} \) heater; \( q_i \) is specific enthalpy drop of extraction steam in \( i_{th} \) heater; \( \gamma_i \) is specific enthalpy drop of drain water in the \( i_{th} \) heater.
\( q, \gamma, \tau \) can be obtained as follows:

\[
q_i = \begin{cases} 
  h_i - h_{d,i} & (i=1,2,3,5,6,7,8) \\
  h_i - h_{w,5} & (i=4)
\end{cases} 
\]  

(20)

\[
\tau_i = h_{w,i} - h_{w,i+1} 
\]

(21)

\[
\gamma_i = \begin{cases} 
  h_{d,i-1} - h_{d,i} & (i=2,3,6,7,8) \\
  h_{d,3} - h_{w,5} & (i=4)
\end{cases} 
\]

(22)

Where, \( h_i \) is the specific enthalpy of extraction steam for the \( i \)th heater; \( h_{w,i} \) is the specific enthalpy of feed-water at outlet for the \( i \)th heater; \( h_{d,i} \) is the specific enthalpy of drain water in the \( i \)th heater.

3.7 Model validation

In this study, a 600 MW(e) coal-fired power plant in China is selected as the reference system and the boiler model and turbine and preheating system model are coded in MATLAB. The off-design and simulation values of 100% load, 75% load and 50% load of boiler are shown in Table 1 while the turbine and preheating system are shown in Table 2. From Table 1 and Table 2, a strong agreement can be seen between the simulation results and the design data. Thus, our model developed in MATLAB is reliable enough to use for further analysis.

### 3.8 Thermodynamic parameters

Solar multiple is an important parameter for the solar thermal power plant, which is the ratio of heat absorbed by the molten salt in the receiver to that transferred to the power block at the design point ($Q_{de}$).

It can be obtained by [1]:

$$SM = \frac{Q_{rec}}{Q_{de}}$$ (23)

The thermal efficiency of STACP system can be expressed:

$$\eta_{STACP} = \frac{P}{Q_{coal} + Q_{solar}}$$ (24)

Where, $P$ is the net power output of the STACP system; $Q_{coal}$ is the thermal energy of the coal.

Boiler’s thermal efficiency can be obtained by:

$$\eta_{boiler} = \frac{Q_{boiler}}{Q_{coal}}$$ (25)

Where, $Q_{boiler}$ is the heat absorbed by the working fluid in the boiler.

Standard coal consumption rate can be obtained by:

$$b_s = 3.6 \times 10^6 \frac{Q_{coal}}{LHV_{st} P}$$ (26)

Where, $LHV_{st}$ is the low heating value of standard coal, which is 29271 kJ/kg.

The CO₂ emissions can be calculated by:

$$Em_{CO_2} = 3.6 \times 10^6 \frac{V_{CO_2} P_{CO_2} Q_{coal}}{LHV P}$$ (27)

Where, $Em_{CO_2}$ is the CO₂ emission; $V_{CO_2}$ is the volume of CO₂ for the combustion of 1 kg coal
\( \rho_{CO_2} \) is the density of \( CO_2 \); LHV is the low heating value of the coal used in this study.

Solar thermal-to-electricity efficiency can be obtained by:

\[
\eta_{solar} = \frac{P_{solar}}{Q_{solar}} \tag{28}
\]

Where, \( P_{solar} \) is the power produced by solar energy. In this study, for a particular load, solar energy is introduced into the boiler and the mass flow rate of superheat steam and reheat steam do not change. Therefore, the power produced by solar energy cannot be obtained easily by the cycle efficiency of the power block. The calculation method of \( P_{solar} \) used in this study has been calculated from literature [24].

4. Case study-results and discussions

4.1 Input conditions

In this study, the STACP system is considered at Lhasa (29.67° N, 91.13° E) and the design point of the heliostat field is set as the solar noon on the summer solstice (21\textsuperscript{st} June). The parameters of heliostat field are shown on Table 3. The DNI values for spring equinox, summer solstice, autumnal equinox and winter solstice are presented in Fig. 4. The temperature of hot tank and cold tank are assumed to be 580 °C and 350 °C. The daily performance is calculated from the time when the solar field starts to work and lasts for 24 hours. The heliostat field starts to work, when the solar altitude angle is higher than 15°. The time of the heliostat starting to work on spring equinox, summer solstice, autumnal equinox and winter solstice are 8:00 AM, 7:00 AM, 8:00 AM and 9:00 AM, respectively.

4.2 Effects of solar load on the boiler

In this section, effects of different solar shares introduced to the boiler under different loads are investigated. Fig. 5 represents the effects of solar load on the standard coal consumption rate.

From the figure, while keeping the parameters of superheat steam and reheat steam unchanged, the maximum solar power that boiler can absorb at 100% load, 75% load and 50% load are 76.4 MWth,
54.2 MW\textsubscript{th} and 23.0 MW\textsubscript{th}, respectively. Considering the real-time power loads from a coal-fired power plant in China over a year averaged up to 90% load most of the time (shown in Appendix A), the design heat load of the solar field in STACP system is set as 68.8 MW\textsubscript{th} (for 100% load shown as 76.4 MW\textsubscript{Wh}). The standard coal consumption rate and CO\textsubscript{2} emissions both show a downward trend with the increase in solar energy. For 100% load, when the solar energy increases from 0 MW\textsubscript{th} to 76.4 MW\textsubscript{th}, the standard coal consumption rate decreases from 273.84 g/kWh to 260.31 g/kWh and the CO\textsubscript{2} emissions decline from 774.70 g/kWh to 736.42 g/kWh. For 75% load, when the solar energy increases from 0 MW\textsubscript{th} to 54.2 MW\textsubscript{th}, the standard coal consumption rate decreases from 284.73 g/kWh to 271.92 g/kWh and the CO\textsubscript{2} emissions decline from 805.51 g/kWh to 769.26 g/kWh. For 50% load, when the solar energy increases from 0 MW\textsubscript{th} to 23.0 MW\textsubscript{th}, the standard coal consumption rate declines from 300.40 g/kWh to 292.18 g/kWh and the CO\textsubscript{2} emissions decline from 849.82 g/kWh to 826.57 g/kWh. The maximum saved standard coal consumption rate at 100% load, 75% load and 50% load are 13.53 g/kWh, 12.81 g/kWh and 8.22 g/kWh, respectively.

Fig. 5 Effects of solar energy on standard coal consumption rate and CO\textsubscript{2} emissions
Fig. 6 Effects of solar energy on boiler and system efficiencies

From the figure, for 100% load, when the $Q_{\text{solar}}$ changes between 0 MWth and 76.4 MWth, the boiler efficiency declines from 94.92% to 93.85%; the system efficiency slightly decreases from 44.91% to 44.57%. For 75% load, when the $Q_{\text{solar}}$ changes between 0 MWth and 54.2 MWth, the boiler efficiency declines from 92.47% to 91.38%; the system efficiency slightly decreases from 43.19% to 42.89%. For 50% load, when the $Q_{\text{solar}}$ changes between 0 MWth and 23.0 MWth, the boiler efficiency declines from 91.84% to 91.18%; the system efficiency slightly decreases from 40.94% to 40.76%. Fig. 7 shows the effects
of solar energy on solar generating power and solar thermal-to-power efficiency. With the increase of $Q_{\text{solar}}$, the $P_{\text{solar}}$ shows an increase trend, while the $\eta_{\text{solar}}$ shows a downward trend. Interestingly, the slope of $P_{\text{solar}}$ for three different loads are almost equal for the change in $Q_{\text{solar}}$. Take 20 MWth as an example, the $P_{\text{solar}}$ for 100% load, 75% load and 50% load are 8.46 MWth, 8.52 MWth and 8.30 MWth, respectively. In addition, the $\eta_{\text{solar}}$ of 75% load is the highest (about 42.6%), while the $\eta_{\text{solar}}$ of 50% load is the lowest (about 41.5%). The solar efficiency for 75% load is higher than 100% load while keeping the main stream conditions same due to extraction pressure is lower for 75% load.

4.3 Effects of solar multiple and thermal energy storage hour
Fig. 8 Effects of solar multiple and TES hour on daily standard coal consumption at (a) 100% load, (b) 75% load and (c) 50% load.

It is shown from Fig. 8 that summer solstice has the lowest daily standard coal consumption and winter solstice has the highest daily standard coal consumption with the same SM and TES hour.
This is due to the available solar energy on summer solstice is highest while the available solar energy on winter solstice is lowest. Table 5 shows the highest and lowest daily standard coal consumption and the requirements to reach minimal daily coal consumption. For 100 % load, when the SM is 2.2 and the TES hours of spring equinox, summer solstice, autumnal equinox and winter solstice are longer than 5 hours, 8 hours, 7 hours and 4 hours respectively to reach the minimal daily coal consumption. This means that SM is the factor that limits the further decline of coal consumption. If SM increases, more coal should be saved further per day. The differences between the highest and lowest coal consumption of spring equinox, summer solstice, autumnal equinox and winter solstice are 61.67 ton, 81.16 ton, 69.98 ton and 46.62 ton, respectively. It indicates it can achieve more profit on summer solstice than that on other typical days with the increase in SM and TES hour. For 75 % load, the differences between the highest and lowest coal consumption of spring equinox, summer solstice, autumnal equinox and winter solstice are 63.21 ton, 83.06 ton, 71.62 ton and 47.71 ton, respectively. For 50% load, these four typical days have the same lowest daily coal consumption (2089.33 ton), which means that the STACP system can operate on the hybrid mode with the maximum solar energy introduced for 24 hours when the requirements are met in Table 5.

The differences between the highest and lowest coal consumption of spring equinox, summer solstice, autumnal equinox and winter solstice are 26.06 ton, 14.17 ton, 21.17 ton and 35.21 ton, respectively. Summer solstice has the lowest difference, because more solar energy can be used on summer solstice and the reduced coal consumption of summer solstice is higher than that of other three days when SM is 0.8 and TES hour is 3 hours.

Fig. 9 Effects of solar multiple and TES hour on thermal storage (75% load)

For example, 75% load scenario, the effects of SM and TES hour on the stored thermal energy throughout a day is shown in Fig. 9. Fig. 9a shows the variation of stored thermal energy through the day on summer solstice with different TES hours with the SM of 2.2. The results indicate that the solar energy collected on summer solstice is in between 9-10 hours of TES capacity. Therefore, the stored thermal energy could be used to meet the energy demand requirement for at least 9 hours on summer solstice. Fig. 9b shows the variation of stored thermal energy throughout the day on winter solstice for different TES hours with the SM of 2.2. It is clearly shown that the characteristic curves for 6 to 10 hours hardly change, so the stored energy can only meet the energy demand requirement for 5 hours TES capacity. Fig. 9c shows the variation of stored thermal energy through the day on summer solstice with different SM when TES hour is 10. It can be seen from the figure
that, when SM = 1.0, the system can operate in the coupled mode for only 11 hours. While, the system can operate in the coupled mode for 23 hours when SM is 2.2. Fig. 9d shows the variation of stored thermal energy through the day on winter solstice with different SM when TES hour is 10 hours. It clearly shows that, for SM = 1.0 and 2.2, the STACP system can operate in coupled mode for 8 hours and 13 hours respectively.

5. Conclusions

In this study, the performance of the STACP system under 100% load, 75% load, and 50% load with different solar shares introduced are investigated and the maximum solar power that boiler can absorb under different loads are determined. Then, the effects of SM and TES hour on the daily performance of STACP system are investigated.

Results indicate that the maximum solar power that a 600 MW_e boiler can absorb at 100% load, 75% load and 50% load are 76.4 MW_th, 54.2 MW_th and 23.0 MW_th, respectively. In addition, the maximum saved standard coal consumption rates are 13.53 g/kWh, 12.81 g/kWh and 8.22 g/kWh, respectively. With the increase of solar power contribution, the boiler efficiency, system efficiency and solar thermal-to-power efficiency show a downward trend, while the power generation from the solar energy shows an upward trend. The studies of SM and thermal storage hour show that the daily coal consumption of summer solstice is lowest and the daily coal consumption of winter solstice is highest for a particular SM and thermal storage hour. Based on the design parameter of the solar field in this study, the study also found that, for all the four typical days, when the SM is 2.2, the solar energy collected per day still cannot meet the energy required for the boiler operating with \( Q_{\text{boiler, max}} \) for 24 hours a day at 100% load and 75% load. While the solar energy collected per day can meet the energy required for the boiler operating with \( Q_{\text{boiler, max}} \) input for 24 hours a day under
50% load, when SM is 1.8.
